Ecological Research Series

THE INFLUENCE OF LAND USE ON STREAM NUTRIENT LEVELS

Environmental Research Laboratory
Office of Research and Development
U.S. Environmental Protection Agency
Corvallis, Oregon 97330

RESEARCH REPORTING SERIES

Research reports of the Office of Research and Development, U.S. Environmental Protection Agency, have been grouped into five series. These five broad categories were established to facilitate further development and application of environmental technology. Elimination of traditional grouping was consciously planned to foster technology transfer and a maximum interface in related fields. The five series are:

1. Environmental Health Effects Research
2. Environmental Protection Technology
3. Ecological Research
4. Environmental Monitoring
5. Socioeconomic Environmental Studies

This report has been assigned to the ENVIRONMENTAL MONITORING series. This series describes research conducted to develop new or improved methods and instrumentation for the identification and quantification of environmental pollutants at the lowest conceivably significant concentrations. It also includes studies to determine the ambient concentrations of pollutants in the environment and/or the variance of pollutants as a function of time or meteorological factors.

This document is available to the public through the National Technical Information Service, Springfield, Virginia 22161.

This report has been reviewed by the Corvallis Environmental Research Laboratory, U.S. Environmental Protection Agency, and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

ABSTRACT

National Eutrophication Survey (NES) data for 473 non-point type drainage areas in the eastern United States were studied for relationships between drainage area characteristics (particularly land use) and nutrient levels in streams. Both the total and inorganic forms of phosphorus and nitrogen concentrations and loads in streams were considered.

The objectives were to: (1) investigate these relationships, as they were evidenced by the NES data and; (2) develop a means for estimating stream nutrient levels from knowledge of "macro" drainage area characteristics.

Mean nutrient levels were considerably higher in streams draining agricultural watersheds than in streams draining forested watersheds. The levels were generally proportional to the percentages of land in agriculture, or the combined percentages of agricultural and urban land use. Variations in nutrient loads (exports) in streams, associated with differences in land use categories, were not as pronounced as the variations in nutrient concentrations. This was apparently due, in large part, to differences in areal stream flow from different land use types.

Regression analyses of the combined percentages of agricultural and urban land uses against both the total and inorganic forms of phosphorus and nitrogen were performed. Equations for these analyses, together with maps illustrating the equations' residuals, offer a limited predictive capability and some accountability for regional characteristics.

ACKNOWLEDGEMENTS

This study would not have been possible without the volunteer manpower supplied by the National Guard of each state. The Guardsmen were responsible for collecting, preserving, and shipping the monthly samples from each designated stream site. Their contribution is sincerely appreciated.

Also gratefully acknowledged are the efforts of Mr. Robert R. Payne (Coordinator, National Eutrophication Survey, Washington, D.C.), who worked with each State water pollution control agency in initiating the survey, and Lt. Col. Louis R. Dworshak (Coordinator of Military Resources, Washington, D.C.), who arranged for the participation of the National Guard in each state.

Most of the data compilation (land use photo interpretation, drainage area and slope measurement, etc.) was accomplished by the following persons: June Fabryka, Madeline Hall, Thomas Jackson, Rose McCloud, Martha McCoy, Ted McDowell, Nola Murri, Michael Ness, James Sachet, and Leta Gay Snyder. Many of these individuals also assisted in graphics compilation and various aspects of basic research.

Dr. Don A. Pierce was primarily responsible for the construction of the prediction models. Both Dr. Pierce and Dr. Dale H. P. Boland provided assistance with computer programming and statistical data manipulation.

Many of the staff at the Corvallis Environmental Research Laboratory contributed input to this study through the logistic support, constructive suggestions, and technical editing. Especially deserving of recognition are Dr. Jack H. Gakstatter and Dr. Norbert A. Jaworski for their solid support and invaluable guidance.

SECTION I

CONCLUSIONS

The analysis of drainage area characteristics and stream nutrient runoff data compiled for 473 non-point source-type drainage areas in the eastern United States indicate that:

1. Streams draining agricultural watersheds had, on the average, considerably higher nutrient concentrations than those draining forested watersheds. Nutrient concentrations were generally proportional to the percent of land in agriculture. Mean total phosphorus concentrations were nearly ten times greater in streams draining agricultural lands than in streams draining forested areas. The difference in mean total nitrogen concentrations was about five-fold.
2. In general, inorganic nitrogen made up a larger percentage of total nitrogen concentrations in streams with larger percentages of land in agriculture. The inorganic nitrogen component increased from about 27% in streams draining forested areas to over 75% in streams draining agricultural watersheds. The inorganic portion (orthophosphorus) of the total phosphorus component stayed roughly at the 40% level regardless of land use type.
3. Differences in nutrient loads in streams associated with different land use categories were not as pronounced as differences in nutrient concentrations. Mean total phosphorus export from agricultural lands was 3.7 times greater than that from forested lands; mean total nitrogen export was 2.2 times greater. Differences in magnitude between the relationships of concentration to land use and export to land use appear to be due mainly to differences in areal stream flow from different land use types, and to a lesser degree, to differences in the mean annual precipitation patterns and mean slope of study areas.

4. Relationships between nutrient levels in streams and "contributing" land use types (percent of drainage area in agricultural land plus the percent in urban land use [% agriculture plus % urban]) were found to be more significant than those considering only one land use type. Separate regression analyses of % agriculture plus % urban against both the total and inorganic forms of phosphorus and nitrogen concentrations were performed. Equations from these analyses offer a limited predictive capability. More complicated equations taking into consideration regional characteristics and/or drainage area characteristics other than land use, afforded only slightly better predictive capabilities over the simple equations.

5. Because of the effects of various aspects on the "flow" portion of the export computation, the most accurate method of predicting export values or stream loads appears to be by using the appropriate model for stream nutrient concentrations and then multiplying by flow.

6. Qualitative refinement of the simple prediction models for total phosphorus and total nitrogen concentrations are provided in maps of each model's residuals. These maps indicate where, in the eastern United States, nutrient concentrations can be expected to be greater, equal to, or less than those predicted by the models.

7. Surface soil pH appeared to have a significant effect on nutrient concentrations in streams, but because of the time and expense involved in procuring accurate surface soil pH data, no further analyses were accomplished.

8. Using a geological classification scheme based on origin and the National Eutrophication Survey nutrient runoff data, no clearly significant relationships were found between geology and phosphorus or nitrogen in streams. It is hypothesized that use of a rock-type classification system based on mineral composition, instead of origin, would reveal significant differences.

SECTION II

INTRODUCTION

HISTORY AND OBJECTIVES

The initial planning for the National Eutrophication Survey (NES) visualized a detailed watershed land use study for each of the approximately 750 lakes which was to be done parallel to the field sampling program. The idea stemmed from a desire to better understand the relationship between lake trophic state and watershed land use. It was hoped that the "fruits" of this effort would be the development of a quick, relatively accurate method of assessing nutrient loadings to lakes based on land use analysis of their watersheds.

The original concept pictured identification and mensuration of overall land use types through aerial photo and topographic map interpretation of the entire watershed of each lake included in the NES. For many reasons, including the unavailability of good photo and/or map coverage for many watersheds or parts of watersheds, the original concept was considerably modified. Presently, the project consists of a study of about 1,000 non-point type drainage areas, mostly within watersheds of lakes being studied by the NES.

As it is now envisioned, the basic objectives of the NES land use study are to investigate the relationships between "macro" drainage area characteristics (particularly general land use) and nutrient runoff in streams with an aim of developing a means for estimating nutrient (nitrogen and phosphorus) runoff based on land use and related geographic characteristics. The project is part of a massive stream and lake sampling program being conducted by NES and includes a large number of drainage areas covering a nationwide variety of climatic and geographic conditions. This affords a unique opportunity to look at the land use--nutrient loadings--eutrophication relationships on

a national scale, and to develop a system utilizing coefficients, or a range of coefficients, to reflect geographical or regional differences.

Because of its ties with the NES field sampling program, which is being accomplished in three phases, the NES land use study follows the same pattern. In the area in which tributary sampling began in the summer of 1972, 133 drainage areas were selected for land use analysis. In the NES study area where sampling was initiated in 1973, 340 drainage areas were selected; and in the remainder of the conterminous United States, where sampling began in 1974, 524 drainage areas were defined. Figure 1 illustrates the distribution of the individual study drainage areas, as well as the overall areas covered by each of the three phases.

Upon completion of data compilation for each of these phases, a report was to be written to present the data collected to date and to present some analyses of these data. This report, as well as providing an explanation of the overall project, presents the data compiled for the first two phases. National Eutrophication Survey Working Paper No. 25 (U.S. Environmental Protection Agency, 1974) presented data compiled through the first phase.

LITERATURE

Recently several extensive literature reviews have been published relating watershed characteristics to non-point source nitrogen and phosphorus concentrations and loads in streams (Uttormark, Chapin, and Green, 1974; Loehr, 1974; Dillon and Kirchner, 1975; and Dornbush, Anderson, and Harms, 1974). These reviews have gathered many of the investigations that, for the most part, have based their results on data collected from a small number of drainage areas within specific geographic regions. In attempting to develop systems for estimating nutrient runoff from land use based on coefficients developed entirely, or in part, from the literature, most reviewers have summarized their findings by presenting a range of values and, in some cases, midpoints

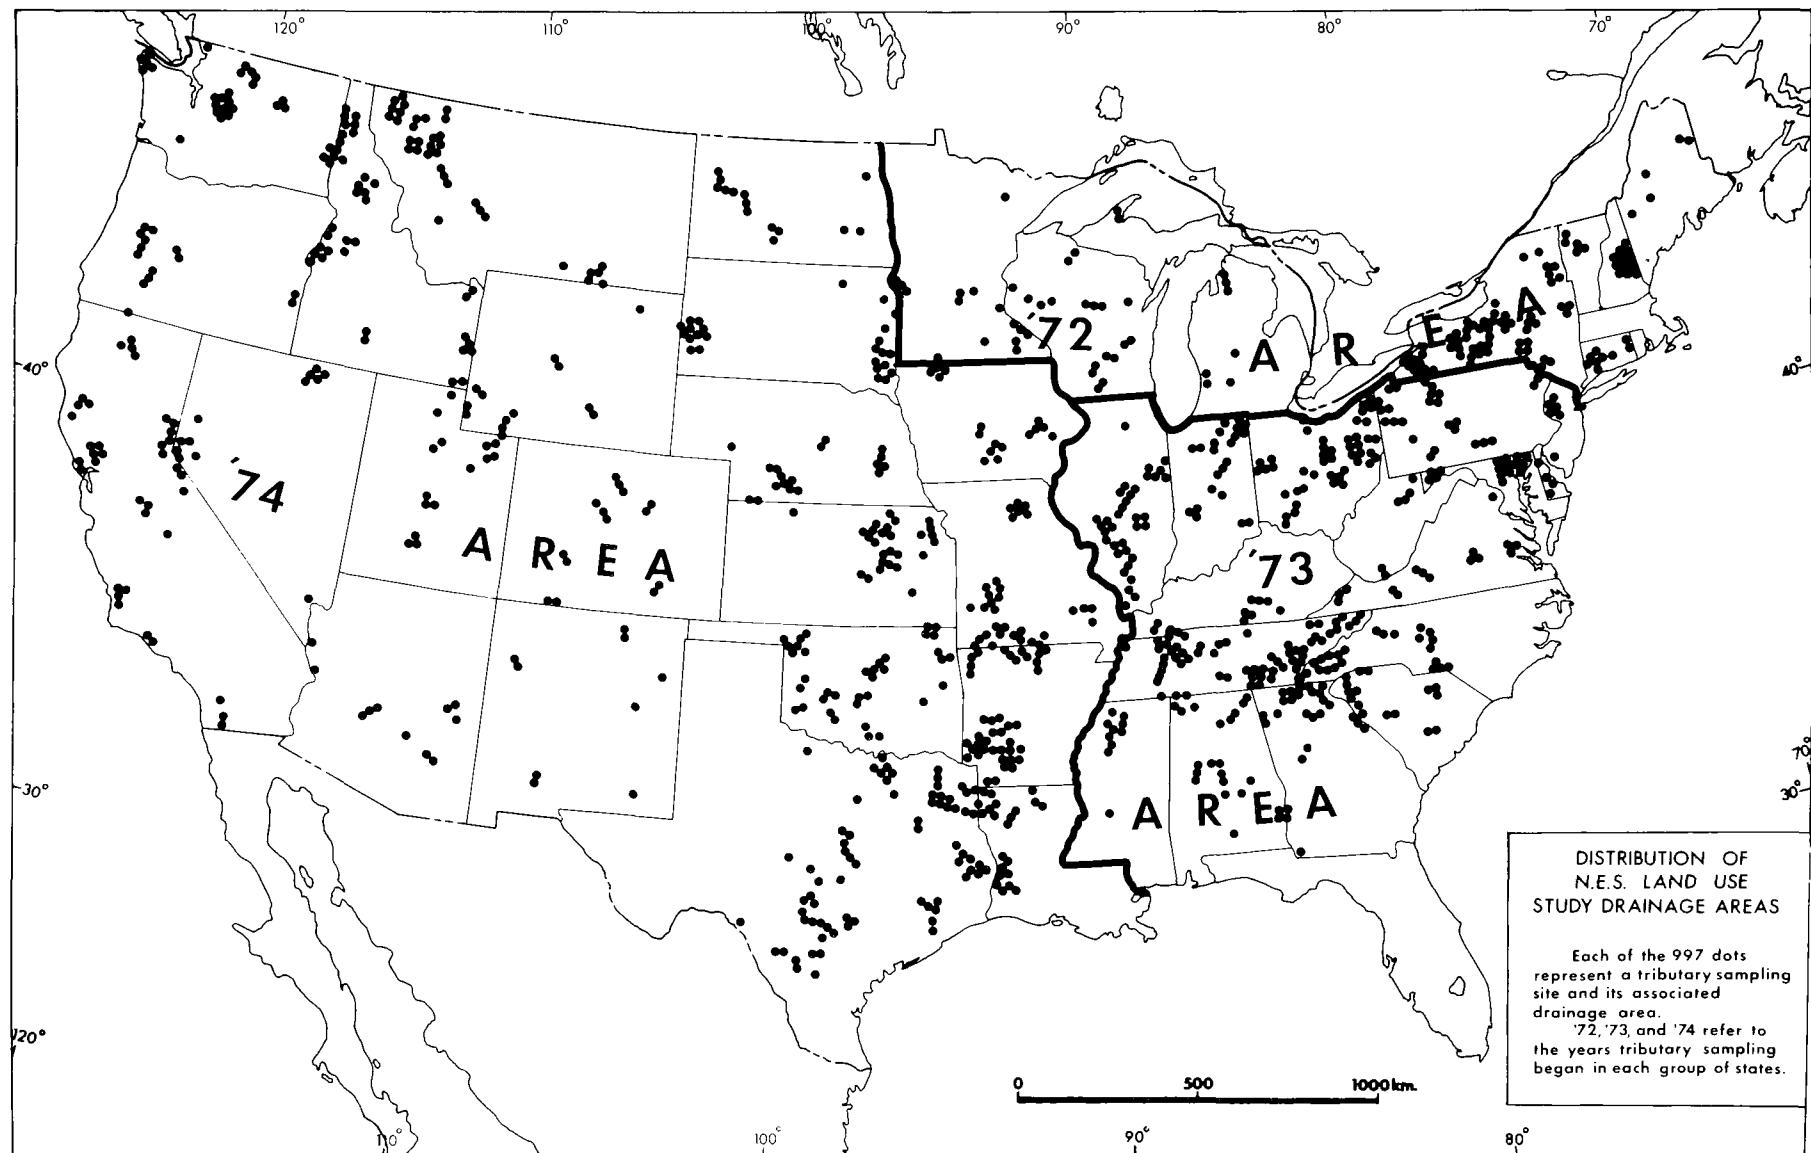

Figure 1. Distribution of individual NES land use study drainage areas.

or averages. Generally, these ranges are quite wide and the midpoints, or other indicators of central tendency, do not vary from one land use type to another as appreciably as one might expect.

It would seem that uniformity in procedure, which is largely lacking from one study (basic investigation) to another, would limit the validity of comparing the results of one with another, or using combined results to establish nutrient loading coefficients. More important, there is an insufficient quantity and an inadequate distribution of data points available from literature sources to study the regional aspects of nutrient runoff. An example of the latter point is shown later in this paper in the section dealing with the effects of geology on nutrients in streams.

STUDY AREA SELECTION CRITERIA

In general, criteria for selecting tributary sampling sites for their associated land use study drainage areas were:

- A. Absence of identifiable point sources.
- B. Availability of usable aerial photography (preferably in scales of from 1:40,000 to 1:80,000) and/or existing land use studies for identifying land use.
- C. Availability of accurate topographic maps for drainage area delineation.
- D. Sufficient relief for clear definition of drainage area limits and for surface runoff to be a significant factor.
- E. Need to encompass a variety of geographic and climatic areas, and obtain, where possible, land use homogeneity within subdrainage areas.

A few exceptions to these criteria were necessary to accomodate study of particular types of areas. Within the 1973 study area, several heavily mined watersheds and several predominately urban watersheds (but without apparent industrial or municipal wastewater treatment facilities) have been included.

It should be noted that an overriding selection constraint was that tributary sampling sites for land use study drainage areas had to be

drawn from those already selected for support of NES lake reports, or had to be selected within a reasonable distance of NES study lake areas to accomodate sampling by the National Guard. At the time selections were being made of drainage areas within the 1972 study area, tributary sampling sites had already been selected and the actual field sampling was underway. Moreover, at that time, the major thrust of the Survey was on point source impact to lakes, particularly that due to municipal wastewater treatment plant discharges. Generally, only "problem" lakes had been selected for study and many of these were in watersheds having "problem" type land uses. Hence, it was somewhat difficult to find drainage areas without point sources; and obtain adequate coverage of all land use types.

At the time tributary sites were being selected for 1973 NES study area lakes, emphasis was still on point sources. However, tributary sampling had not yet begun in several of the 1973 area states which allowed an opportunity to choose additional sites where their inclusion was warranted by land use homogeneity and other factors suitable for land use and nutrient runoff analyses.

Selection of tributary sampling sites for land use study drainage areas in the 1974 area (west of the Mississippi) was made under more ideal conditions. By this time water research mandates had been revised by passage of Public Law 92-500. These revisions resulted in a broadening of Survey objectives to include assessment of relationships of non-point sources to lake nutrient levels. In addition, lake selection criteria were modified to no longer include just "problem" lakes, but lakes representative of a full range of water quality. This presented a better balance of lake watersheds and land use types as well as lake types. In several instances, where it was necessary to achieve a better geographic distribution of drainage areas or obtain a better balance of land use categories, sites were selected outside NES lake watersheds.

OVERALL STUDY AREA DESCRIPTION

The geographic area for which data are presented encompasses most of the United States east of the Mississippi River including Minnesota. All of Florida, some of the Gulf and Atlantic coasts and northwestern Minnesota were not included because of insufficient relief to allow accurate drainage area delineation and/or to enable surface runoff to be a significant factor. Although the overall study area does not exhibit the physiographic or climatic extremes found in the remainder of the conterminous United States west of the Mississippi River, there is considerable diversity. Landforms range from flat to rolling plains along the Atlantic and Gulf coasts and in the interior lake states, to hills, dissected plateaus and low mountains in the northeast-southwest trending Appalachian Highlands. Physical subdivisions are shown in Figure 2, and the general geology of the area is shown in Figure 3. The climate in the northern half of the area is humid continental and in the southern half, humid subtropical. The northern half is characterized by humid, warm to hot summers and cold winters; the southern half, hot humid summers and cool winters. Yearly temperature ranges are generally greater toward the interior. Most of the study area receives between 80 to 120 centimeters of precipitation per year (Figure 4). Extreme mean annual precipitation varies from less than 60 cm. in western Minnesota to over 160 cm. in parts of the Appalachians.

SECTION III

DATA COLLECTION METHODS

DRAINAGE AREA MEASUREMENT AND LAND USE IDENTIFICATION

Following tributary site selection, individual drainage areas were delineated on U.S. Geological Survey (USGS) topographic maps and their areas determined by use of a compensating polar planimeter or an electronic planimeter. General land use identifications were made using late-date aerial photography and/or recent land use maps. Land use categories included: (1) forest, (2) cleared-unproductive, (3) agriculture, (4) urban, (5) wetland, and (6) other (including barren, extractive and open water). These types roughly correspond in level of classification to Level I of the recently developed USGS Land Use Classification System (U.S. Department of Interior, 1972).

LAND USE PERCENTAGE COMPUTATION

For each drainage area, percent coverage of each land use type was compiled by use of equidistant dot pattern overlays. The dot patterns were placed non-selectively over the USGS map overlays on which land use units had been outlined. To determine the land use percentage for a given drainage area, the number of dots that fell on each land use category was totaled; each total was multiplied by 100, and the resulting products were divided by the number of dots falling in the drainage area. Dot pattern densities varied from one drainage area to another depending on the overall size of the drainage area; generally, the larger the area the less dense the dot pattern. At least 400 dots per drainage area, but preferably less than 800 were needed for a valid determination of percent coverage.

ANIMAL UNIT DENSITY COMPUTATIONS

It is generally accepted that animal wastes are major contributors to the nitrogen and phosphorus in agricultural land runoff (Holt, Timmons, and Latterell, 1970; Holt, 1971; Robbins, Howells, and Kriz, 1971). Early in this study, it seemed some mechanism should be developed to analyze this aspect of agricultural runoff. Because of shifts in agricultural land use, particularly from season to season and year to year, it seemed impractical or impossible to accurately separate pasture from cropland. A more expeditious method was to determine overall animal densities (i.e., animal units per acre of subdrainage area).

For the most part, animal unit densities for each drainage area were computed from U.S. Census of Agriculture figures, other literature sources and personal communications (Johnson and Mountney, 1969; Miner and Willrich, 1970; Miner, 1971; Anonymous, 1972; Anonymous, 1973; Anonymous, 1974; Arscott, 1975; Harper, 1975; Hohenboken, 1975; and Miner, 1975). The quantities of total nitrogen and total phosphorus produced annually by common farm animals were also compiled from these sources (Table 1).

TABLE 1. ANIMAL NUTRIENT PRODUCTION (kgs/yr/animal)

	Total P	Total N
Cattle	17.60	57.49
Hogs	3.23	9.68
Sheep	1.47	10.06
Poultry		
Layers	0.16	0.42
Broilers	0.09	0.39
Turkeys	0.39	0.84

These data, together with Census of Agriculture figures by county, were used to compile animal unit densities per drainage area using the

following equation:

$$A_p = \left[\frac{\left(\frac{1}{A_c} \right) \left(\frac{D_a}{1} \right) \frac{C_a + (0.184 \cdot H) + (0.0084 \cdot S) + (0.0093 \cdot P_1) + (0.0011 \cdot P_b) + (0.0222 \cdot P_t)}{1}}{1} \right]$$

and

$$A_n = \left[\frac{\left(\frac{1}{A_c} \right) \left(\frac{D_a}{1} \right) \frac{C_a + (0.169 \cdot H) + (0.175 \cdot S) + (0.0073 \cdot P_1) + (0.0015 \cdot P_b) + (0.0147 \cdot P_t)}{1}}{1} \right]$$

where: A_p = Animal units per square kilometer for Total P;

A_n = Animal units per square kilometer for Total N;

A_c = Total agricultural land (by county) in square kilometers;

D_a = Percent of subdrainage area in agriculture;

C_a = Total cattle and calves (by county);

H = Total hogs and pigs (by county);

S = Total sheep and lambs (by county);

P_1 = Total layers (by county);

P_b = Total broilers (by county); and

P_t = Total turkeys (by county).

For drainage areas located in more than one county, weighted unit densities were determined based on the amount of each drainage area's agricultural land in each county. The coefficients have been adjusted to reflect average animal weights relative to an average weight for cattle and calves (same sources as for Table 1). It should be noted that coefficients for poultry take into consideration average life spans and broods per year.

GEOLOGY IDENTIFICATION

Some recent works on non-point source nutrients in streams have given as much or more emphasis to the effects of geology than to the effects of land use (Dillon and Kirchner, 1975; Likens and Bormann,

1974; Thomas and Crutchfield, 1974). Using the paper by Dillon and Kirchner as a guide, the following general breakdown was used to classify NES study subdrainage areas:

1. Sedimentary rocks or deep alluvium (>61 meters) with some or all limestone.
2. Sedimentary rocks or deep alluvium (>61 meters) without any mapped limestone.
3. Igneous rocks of volcanic origin.
4. Metamorphic rocks.
5. Igneous rocks of plutonic origin.

Where drainage areas included two of the above classifications, combinations were shown with the predominant type first. Sources for these data were mostly state and federal government geologic maps of varying dates and scales; although most were of individual states at scales ranging from 1:250,000 to 1:500,000.

SLOPE COMPUTATIONS

For each drainage area mean slope was calculated using an equidistant dot pattern overlay. Less dense patterns were used for this work than were used for computing land use percentages. For this procedure, 40-80 dots per drainage area were used. The overlays were placed randomly over the topographic maps on which the drainage areas had been outlined. Then, using an appropriate slope indicator, the percent of slope for the points under each dot was calculated. The data were then totaled and divided by the total number of points falling in the drainage area. The slope indicators used were transparent templates indicating percent of slope from distances between map contours, adjusted for map scale and contour interval.

OTHER PROCEDURES

Explanations of the following procedures are given in NES Working Paper No. 1 (U.S. Environmental Protection Agency, 1974); and NES Working Paper No. 175 (U.S. Environmental Protection Agency, 1975):

1. Tributary sampling methods and handling.
2. Analytical methods (stream samples).
3. Nutrient loading estimates.
4. Stream flow estimates.

It should be noted that nutrient exports were computed using "normalized" flow data (adjusted for seasonality and sampling year) from the USGS and drainage area measurements as determined by NES. For a few tributary sampling sites, where the USGS had not provided flow estimates, they were calculated by NES from runoff patterns in adjacent, overlapping, or nearby areas for which USGS estimates were provided. Loadings for all drainage areas in this study were estimated according to the following equation:

$$\text{Annual Load} = (C)(F)(31,356)$$

where: C = Mean annual concentration in milligrams per liter, and

F = Mean normalized annual stream flow in cubic meters per second.

The factor 31,356 is used to adjust the concentration and flow data in order to obtain loads in kilograms per year. The annual loads were then divided by the area (in square kilometers) of their respective watershed.

SECTION IV

DISCUSSION OF RESULTS

This section discusses the analysis of land use, other drainage area characteristics, and stream nutrient runoff data compiled for drainage areas within the first two groups of states covered by the NES. The raw data are presented in Appendix A and the distribution of the 473 data points (comprising the 1972 and 1973 areas) are illustrated in Figure 1. Subsequent reports will present data on the 524 drainage areas west of the Mississippi River where tributary sampling is still in progress.

AREAL DISTRIBUTIONS OF DATA

After compiling the data presented in Appendix A, several types of these data were sorted into classes and plotted on maps of the eastern half of the United States using a graduated color scheme. It was theorized that this might aid in uncovering correlations, regional patterns, and (by comparison with maps of other "macro" aspects such as physiographic regions, geology, soils, and climate) possible covariants. Maps were compiled for total P concentrations, total N concentrations, total P export, total N export, % agriculture plus % urban, flow per unit area per year, and mean slope. Maps illustrating the most significant patterns are included in black and white as Figures 5 through 8.

The map (Figure 5) of various classes of percent of drainage area in agricultural land use plus the percent in urban land use (% agriculture + % urban) revealed what might be expected from a knowledge of general land use patterns in the eastern United States. High percentages of land in agricultural and urban uses were present in the midwest farming and

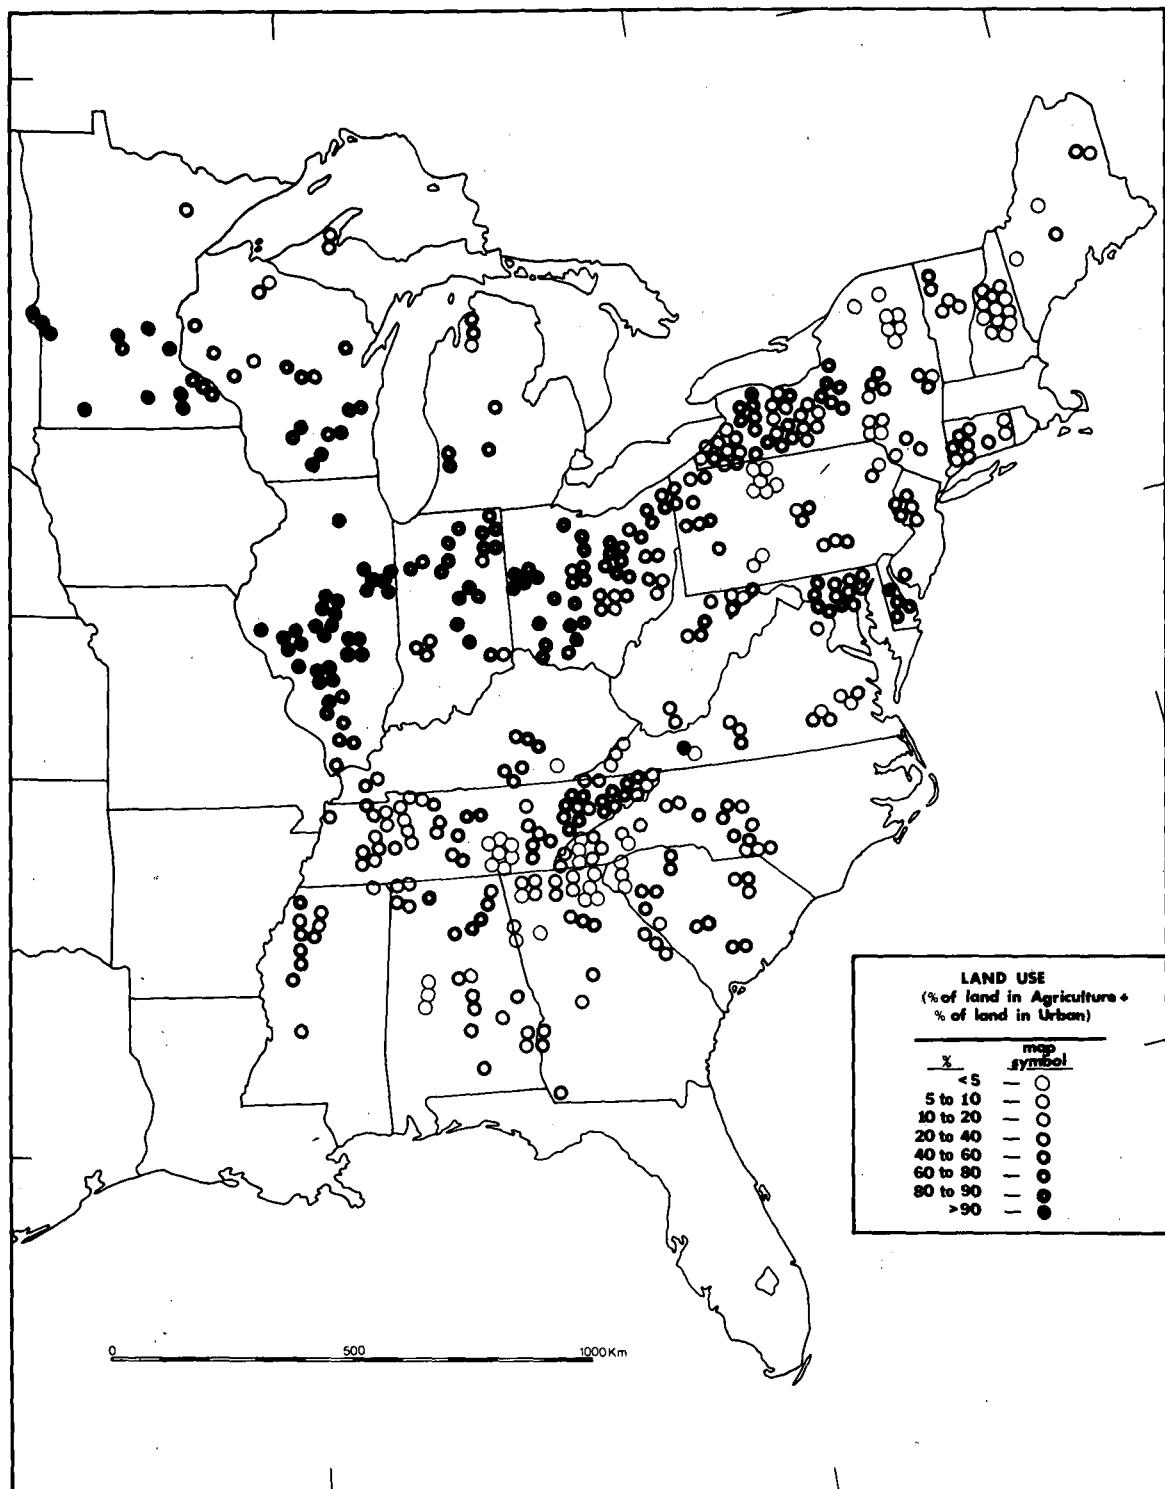

Figure 5. Areal distribution of percentages of land in agricultural and urban land use in study areas in the eastern United States.

manufacturing belt from the northwest corner of Pennsylvania through Ohio, Indiana, Illinois, and southern Wisconsin to southern Minnesota. Agricultural and urban land uses also predominated in Delaware and east-central Maryland, parts of the "ridge and valley" portion of the Appalachians, and patches of the "finger lakes" area of New York. Low percentages of these land use types were present in much of New England, northern Pennsylvania, and numerous places throughout the Appalachians and Southeast.

The map (Figure 6) illustrating the areal distribution of mean total phosphorus concentrations data uncovered a pattern roughly similar to that of the land use map, and hence a possible correlation. Comparison of the two maps (Figures 5 and 6) revealed several groups of drainage areas with notably lower phosphorus concentrations than might be expected from land use alone. These areas were in east-central Maryland, Pennsylvania, and parts of central and eastern Ohio and New York (particularly the finger lakes area).

The map (Figure 7) of total nitrogen concentrations, like that for total P, had a pattern similar to the map of land use. Some noteworthy differences were: (1) particularly high total nitrogen concentrations in the Midwest and middle Atlantic region, from Maryland and Delaware through New Jersey and southwestern Connecticut; and (2) very low values in the mixed farming areas of the central and southwestern Appalachians and remainder of the Southeast.

Examination of the areal distributions of both total P and total N export values revealed some similarities in pattern to that of land use, but far less than the likenesses between nutrient concentrations and land use. The distribution maps of slope and flow (discharge/unit area) values (Figure 8) were constructed to study the possible relationships of these factors to the differences in correlation between nutrient concentration and land use, and nutrient export and land use. Analyses of these data will follow in other sections of this paper.

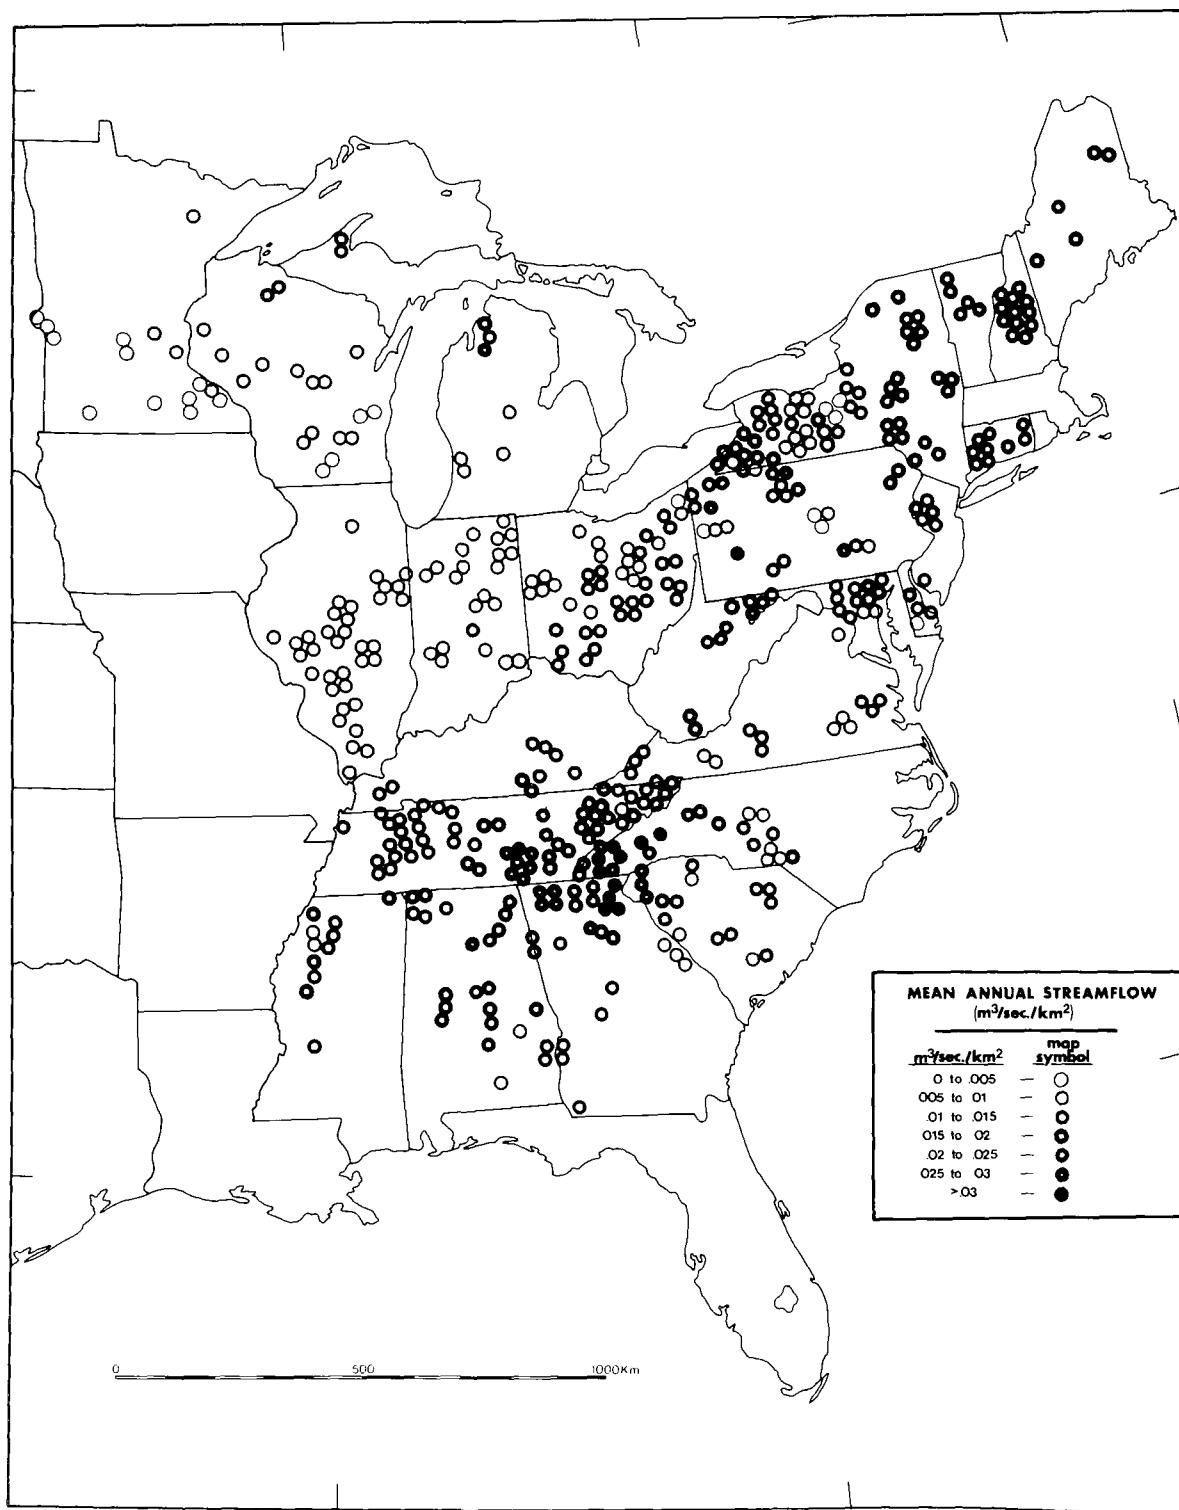

Figure 8. Distribution of mean annual areal flows in streams draining study areas in the eastern United States.

OVERALL LAND USE-NUTRIENT RUNOFF RELATIONSHIPS

Category Definitions

Individual drainage areas were assigned overall land use categories according to the following criteria:

1. Forest; other types negligible
 - a. >75% forest (including forested wetland)
 - b. <7% agriculture
 - c. <2% urban
2. Mostly forest; other types present
 - a. >50% forest
 - b. not included in forest category
3. Mostly agriculture; other types present
 - a. >50% agriculture
 - b. not included in agriculture category
4. Agriculture; other types negligible
 - a. >75% agriculture
 - b. <7% urban
5. Urban
>39% urban
6. Mixed; not included in any other category

General Analysis

The relationships between these overall land use categories and nutrient runoff are illustrated in Figures 9 through 12. It should be emphasized that these graphs contain mean annual nutrient stream values from the entire 24-state area and do not reflect regional relationships. For example, one should not conclude from Figure 9 that total phosphorus concentrations in streams draining "mostly agricultural" areas in Vermont and New York will average about 0.066.

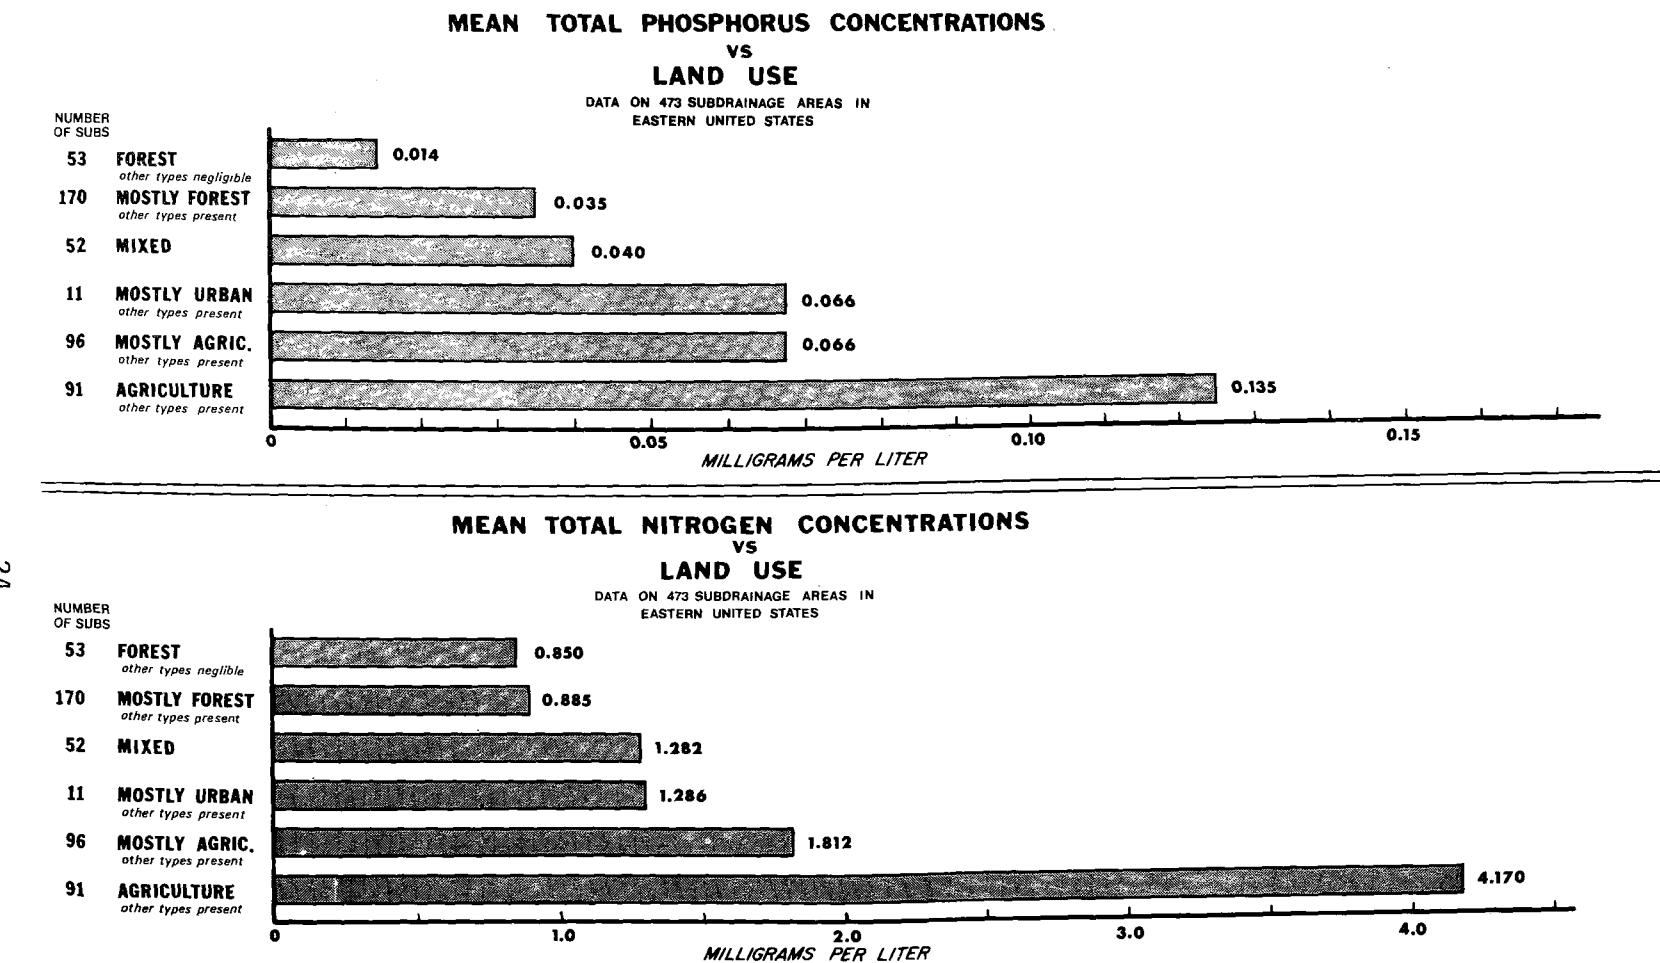

Figure 9. Relationships between general land use and total phosphorus and total nitrogen concentrations in streams.

From analysis of other values in the same geographical region, an average regional value would probably be somewhat smaller. By the same token, one would expect higher concentrations in streams draining "mostly agriculture" areas in the Corn Belt. Obviously, other interrelated factors such as agricultural practices, slope, soils, climate, etc., are important.

However, Figures 9 through 12 illustrate some significant overall relationships. Nutrient concentrations are significantly lower in streams draining forested areas than in streams draining areas that are used primarily for agricultural purposes. This is true for both nutrients but to a greater degree for total phosphorus than total nitrogen. Total phosphorus concentrations are roughly 10 times higher in streams draining predominantly agricultural watersheds than in streams draining forested watersheds. On the other hand, mean total nitrogen stream concentrations only show a difference of 5-fold from forested watersheds to agricultural watersheds. Interestingly, based on these mean concentration values, phosphorus would be expected to be limiting in surface waters draining either forest or agricultural areas. The total nitrogen to total phosphorus ratios are 60:1, 25:1, 32:1, 27:1 and 31:1 for "forest", "mostly forested", "mixed", "mostly agriculture" and "agriculture" areas, respectively. Generally phosphorus is the limiting nutrient as long as the N:P ratio exceeds 14:1 (Vollenweider, 1968). Also noteworthy is the fact that Figure 9 shows nearly the same mean values as did similar graphs prepared earlier for the 143 subdrainage areas covered by Working Paper No. 25 (U.S. Environmental Protection Agency, 1974).

Figure 10 shows the relationships of overall land use categories to mean concentrations of orthophosphorus and inorganic nitrogen. For orthophosphorus, the relationships appear about the same as those between total phosphorus and land use. Regardless of land use, mean orthophosphorus concentrations represented from 40% to 43% of the mean total phosphorus, except with predominantly urban drainage areas of which there were only 11.

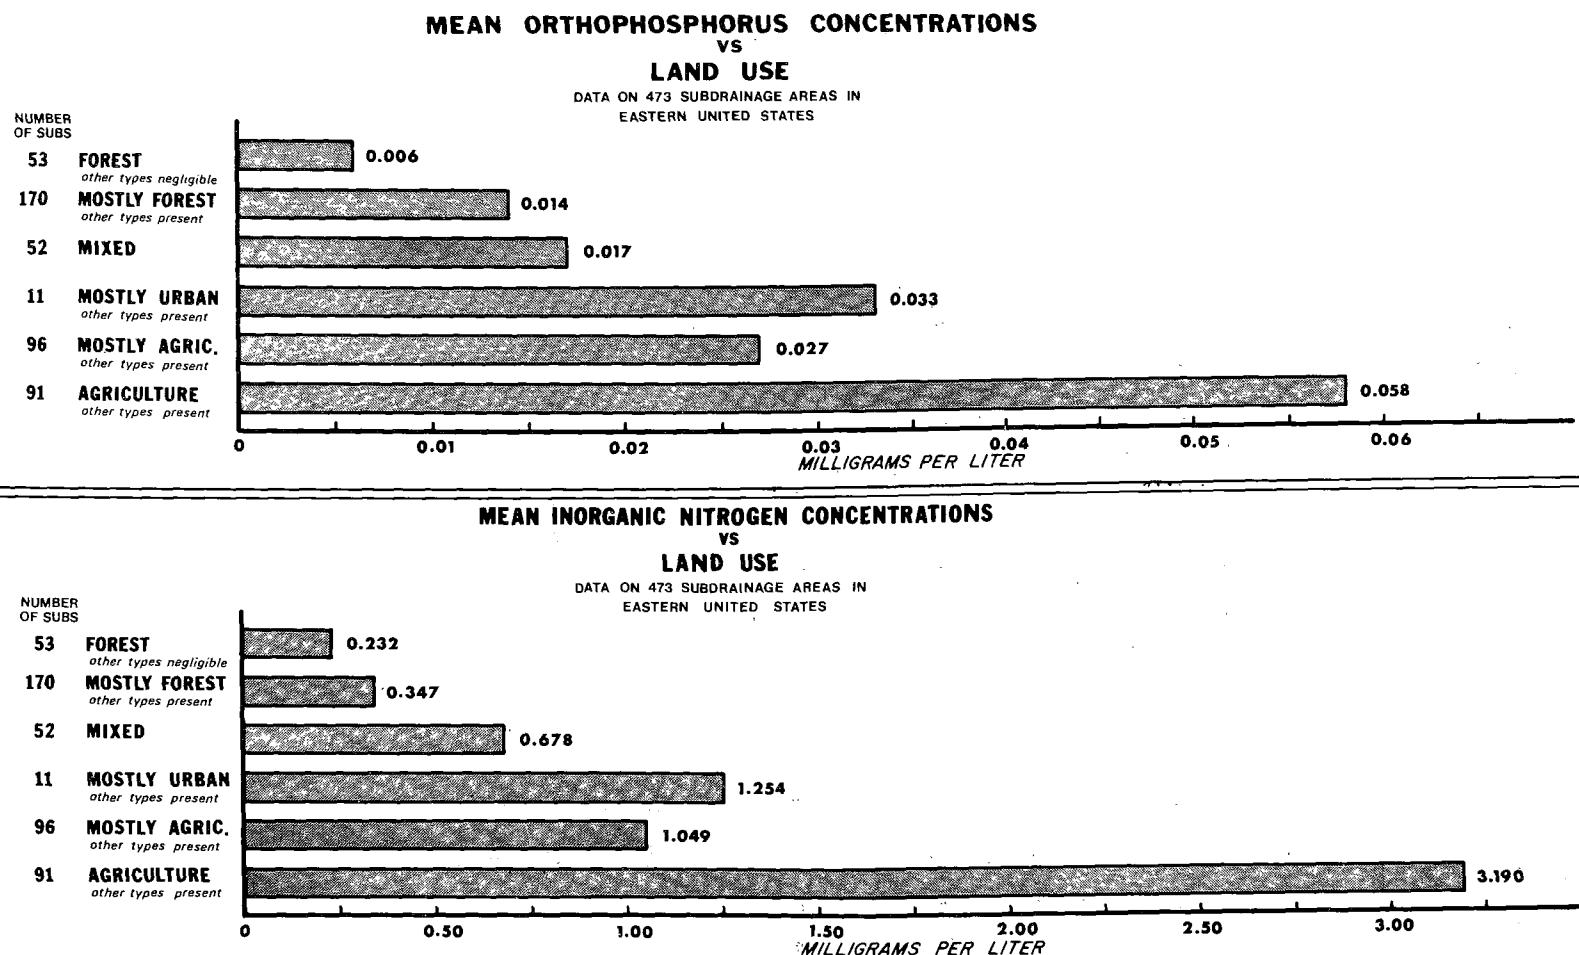

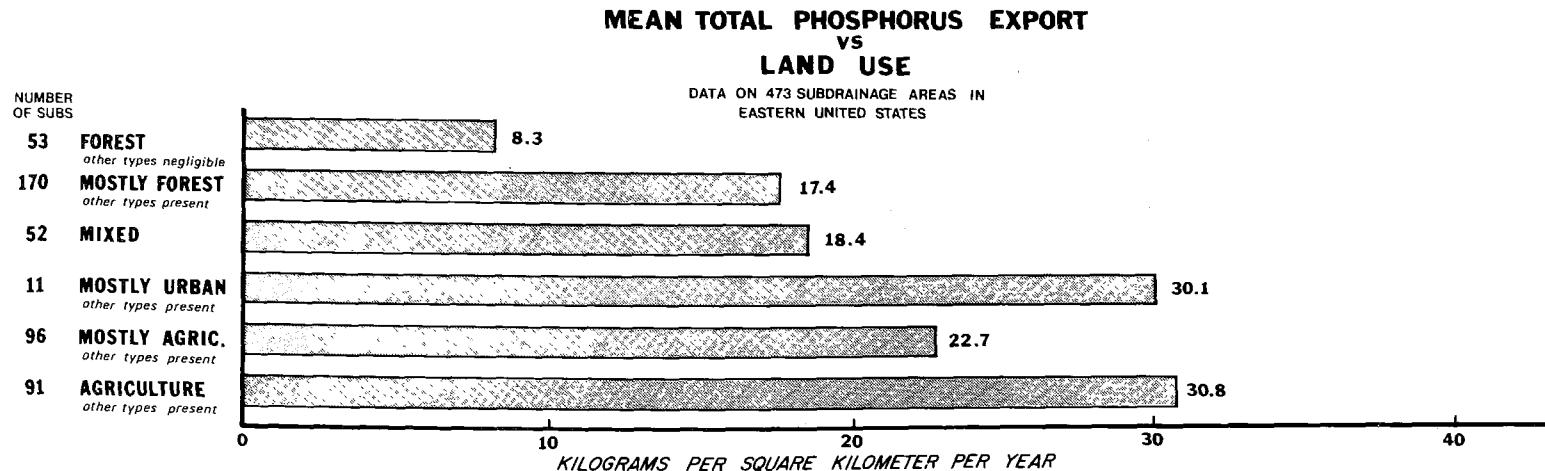

Figure 10. Relationships between general land use and orthophosphorus and inorganic nitrogen concentrations in streams.

By comparing Figure 9 with Figure 10, one can see that mean inorganic nitrogen concentrations represent an increasing percentage of mean total nitrogen concentrations with increased amounts of agricultural land use. The percentages are 27%, 39%, 53%, 57% and 76% for "forest", "mostly forest", "mixed", "mostly agriculture" and "agriculture" categories, respectively. This probably reflects the use of inorganic nitrogen fertilizers and the high water solubility of inorganic nitrogen compounds.

Mean inorganic nitrogen represented nearly 98% of the mean total nitrogen in the 11 "mostly urban" drainage areas. As mentioned earlier, no industrial or municipal waste treatment facilities or outfalls were known within these urban areas. However, the time and expense that would have been involved did not allow field checking. The data probably reflect effects of runoff from streets and lawns, and to some extent, the effects of septic tanks.

The nutrient loads per unit area of watershed for both forms of phosphorus and nitrogen are shown in Figures 11 and 12. These data indicate that the differences in export from different land use categories are considerably less pronounced than the differences in nutrient concentrations. Total phosphorus export was only 3.7 times greater from agricultural lands than from forested lands and total nitrogen export, only 2.2 times greater. Partial explanation of the difference in the relationships of concentrations to land use and export to land use apparently lies in the differences in stream flow (per unit area per year) between agricultural lands and forested lands. Regression analysis of flow (cubic meters per square kilometer per year) to the percent of subdrainage area in forest revealed a fairly good correlation ($r = 0.64$). This was probably due to greater slopes and thinner soils in the forested areas as opposed to the agricultural areas. The correlation coefficient between mean slope and the percent of drainage area in forest was 0.65 and the correlation coefficient for flow and the mean slope was 0.60. One would expect direct surface runoff to increase with increased slope, but

28

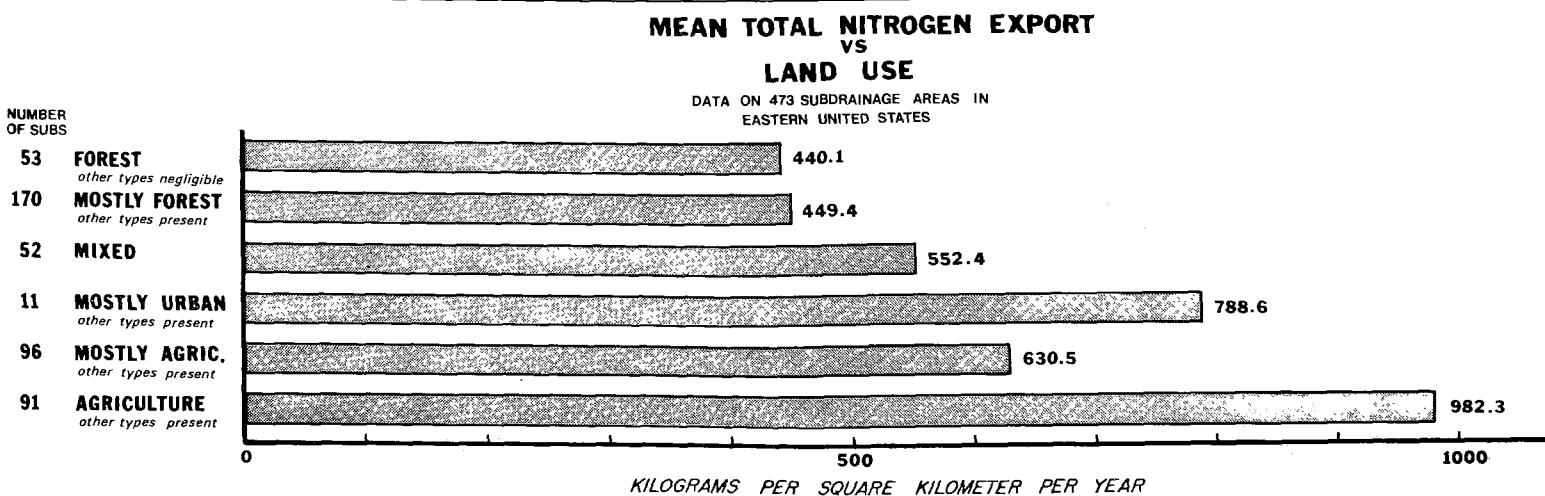

Figure 11. Relationships between general land use and stream exports of total phosphorus and total nitrogen.

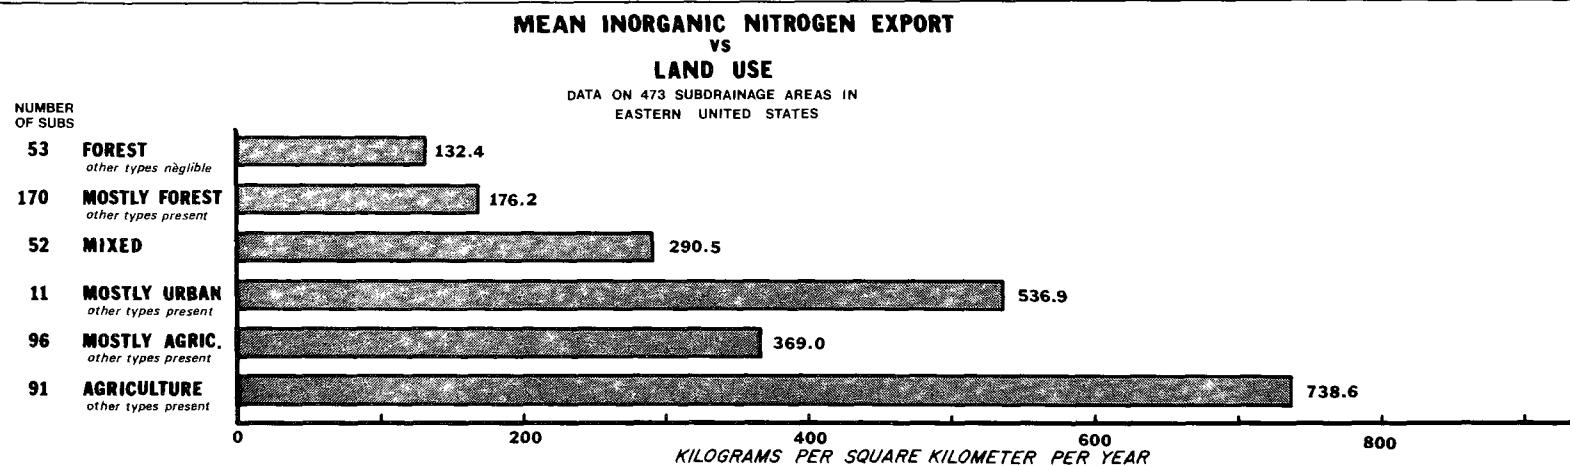

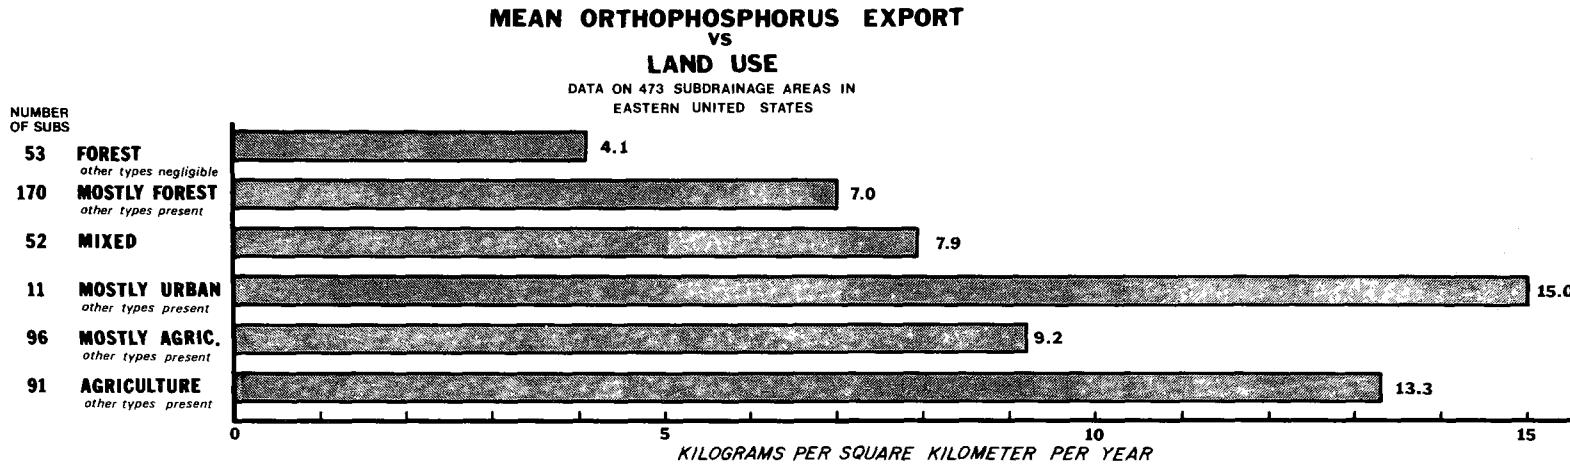

Figure 12. Relationships between general land use and stream exports of orthophosphorus and inorganic nitrogen.

not average annual stream discharge as was shown with these data; therefore, one or more covariants seem probable.

Some additional explanation of the difference between relationships of nutrient concentrations to land use and nutrient export to land use may be found in differences in mean annual precipitation patterns relative to study area locations. From analysis of study area locations, it appeared that most of the forested drainage areas were located in regions receiving slightly greater average annual precipitation amounts than regions where most of the agricultural watersheds were located. Greater annual precipitation amounts would help explain the greater flow values in forested study areas. However, the correlation between percent of subdrainage area in forest and mean annual precipitation was found to be statistically less significant ($r = 0.56$) than the correlation between slope and forest.

The data also indicate that urban land usage seems to have a pronounced effect on the amount of export. Again, the cause is probably increased flow rates, but in this case it was more likely because of greater areas of impervious surfaces.

For additional help in understanding the differences in the relationships between concentrations and land use, and export and land use, it is important to recognize that the drainage areas included in this study are not control plots. Rather, they are natural drainage areas which represent typical land use- and geographically-related characteristics in their respective areas. If one were studying control plots where slope, soil type, and climate conditions were similar from one plot to another, one would expect a significantly higher nutrient export rate (as well as a higher nutrient concentration) from plots in agricultural land use than from forested plots. Runoff as well would probably be somewhat greater from agricultural plots than from forested plots. Natural drainage areas, on the other hand, possess different topographic, soils, and climatic characteristics. These characteristics are important in determining land use in the first place. In general, flat to rolling terrain and rich soils, such as are found in southern Minnesota, lend

themselves to agricultural land use. Conversely, where the terrain is too mountainous or dissected or the soil too poor for agriculture to be economically feasible, such as in much of New England, forests are allowed to predominate.

The fact that study subdrainage area sizes vary, and that those categorized as forest were considerably smaller than any other category, suggested that size might have a bearing on nutrient concentrations and/or stream flow. If either factor was related to size, then export would also be related. However, analysis of these data revealed no significant correlations.

The frequency polygons (Figures 13 through 16) illustrate how the nutrient concentration and export data were distributed for each land use type. Comparison of these polygons with Figures 9 through 12 show the data for forested drainage areas were grouped more tightly around the mean values than were data for agricultural drainage areas. The irregular data distributions for urban drainage areas are of questionable significance, mainly because of the small sample size.

Regionality

To refine the relationships of land use to nutrient runoff shown by the bar graphs and frequency polygons, a regional analysis is presented (Figures 18 through 21). Because the data appeared to be more closely related to land use than any other one "macro" element, it seemed a regional breakdown should be based on general land use and related geographical aspects that were instrumental in determining land usage. A modified breakdown of Austin's Land Resource Regions (1972) fits this description and the overall data distribution (Figure 17).

These graphs help explain where, within a given data distribution (in Figures 13 through 16), one is most likely to find concentration or export values based on regional location, but their use is limited. Where

sample sizes for a particular land use category are small, the concentration or export values for that category are of questionable use. For example, it is not safe to assume that, based on data for two drainage areas, streams draining "agriculture" areas in the Piedmont and Coastal Plain Mixed Farming Region (P.C. Region) are going to have generally higher total nitrogen concentrations than streams in the Corn Belt and Dairy Region (C.D. Region). As a matter of fact, from looking at the data for "mostly agriculture" areas, where the sample size was fairly large for both regions, one would probably estimate total nitrogen concentrations to be slightly lower in the P.C. Region than the C.D. Region. Also, because of the "room" within these overall land use categories (e.g. drainage areas categorized "forest" may contain from 75 to 100 percent forest and 0 to 6.9 percent agriculture), where sample sizes are small on either end of the overall land use category "scale" for a given Land Resource Region, the amount of that land use type within those few drainage areas can be expected to be smaller than it would be with a region where sample sizes are larger on the same end of the "scale".

INDIVIDUAL RELATIONSHIPS AND PREDICTION CAPABILITY

"Contributing" Land Use Types and Stream Nutrients

Figures 22 through 27 illustrate the relationships between land uses generally considered nutrient contributing (% agriculture plus % urban) and nutrients in streams. Several ways of looking at the effects of land use on nutrient concentrations or loads in streams were investigated. In general, nutrient loads increased with increased percentages in agricultural land usage, and decreased percentages in forested land. Little to no correlation was found between nutrient levels and percent of land in either cleared-unproductive, urban or wetland. This was expected because of the probable masking effects by agriculture and forest.

Since increased or decreased percentages of all general land use types appeared to have some effect on nutrient levels, a land use ratio of "contributing" (agriculture + urban) over "non-contributing" (forest + cleared-unproductive + wetland) types was investigated for its utility as a single factor including all land use types. Generally, relationships between these ratios and nutrient levels in streams were found to be more significant than those considering only one land use type. It was then determined that use of just the numerator (% agriculture plus % urban) from the ratio provided more easily understood land use values and eliminated the graphing problems encountered by working with values to infinity.

Use of "% agriculture plus % urban" to relate effects of land use on nutrient levels in streams appears to be appropriate where agriculture and/or forest comprise the predominant type(s). These two land use categories comprise the bulk of the land use data gathered for this study, but also constitute by far the predominant land use in the eastern half of the United States. The use of "% agriculture plus % urban" even seems to compensate for minor amounts of the other general land use types. However, its use is probably unsatisfactory for predicting or estimating nutrient concentrations or loads for areas where either urban, cleared-unproductive, or wetland land use types predominate; particularly where urban predominates. Insufficient data have been collected for these types.

"Contributing" Land Use Types and Nutrient Concentrations

Figure 22 shows the relation between mean total phosphorus concentrations in streams and "% agriculture plus % urban". The equation for the regression line shown in Figure 22 is:

$$\text{Log}_{10} (\text{PCONC}) = -1.831 + 0.0093 (\% \text{ agric.} + \% \text{ urban}) \quad (1)$$

The correlation coefficient for this relationship is 0.73. The utility of the equation for predictions is illustrated in Table 2.

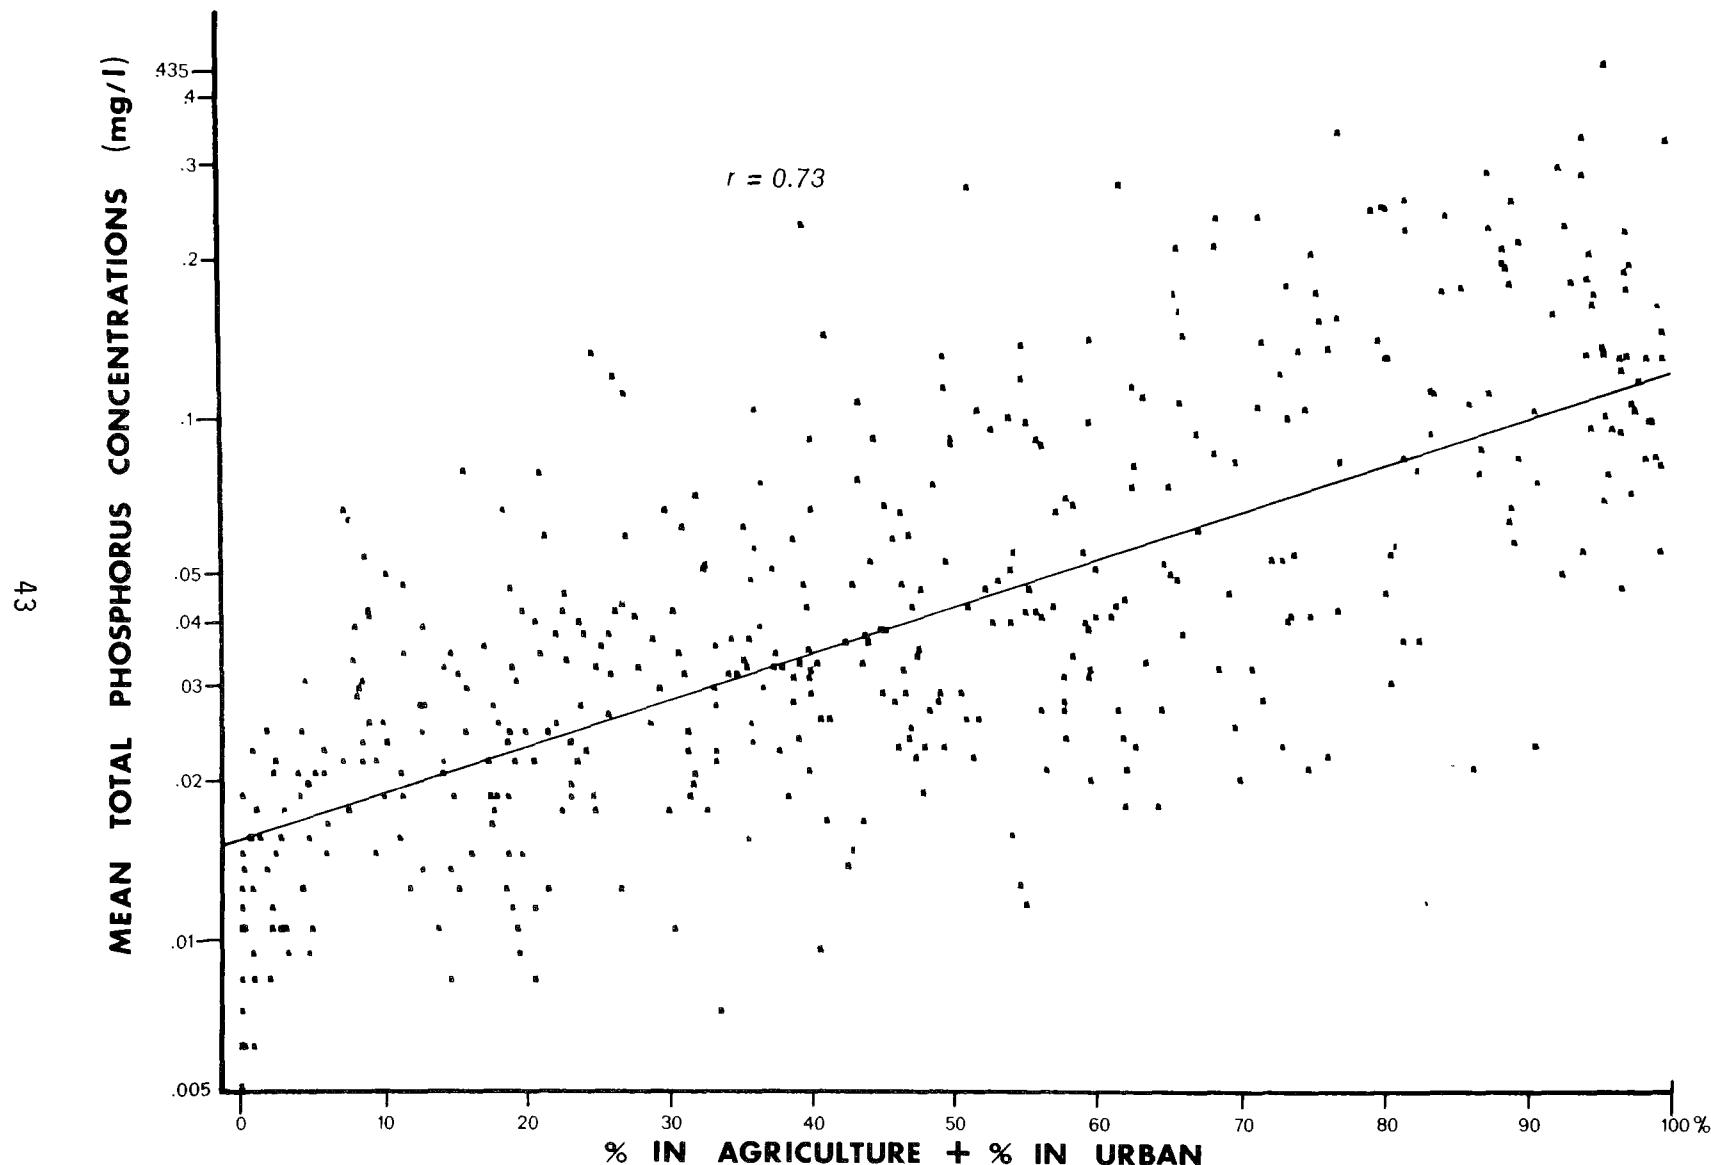

Figure 22. Scattergram of "contributing" land use types related to phosphorus concentrations in streams.

TABLE 2. PREDICTED MEAN TOTAL PHOSPHORUS CONCENTRATIONS (mg/l)

% Ag + % Urb	Avg. PCONC	67% Limits	95% Limits
0	0.015	0.008-0.027	0.004-0.050
25	0.025	0.014-0.046	0.007-0.086
50	0.043	0.023-0.079	0.013-0.146
75	0.074	0.040-0.135	0.022-0.249
100	0.126	0.068-0.231	0.037-0.427

For example, for streams draining areas with a combined agriculture plus urban land use percentage of 25%, mean total phosphorus concentrations average 0.025 mg/l. However, because of the variation around this prediction, there is only a 67% probability that the true value will fall in the range 0.014 to 0.046 mg/l, and there is a 95% confidence that the value will be within the wider range of 0.007 to 0.086 mg/l.

The next most complex model makes a correction in the sense that streams in the Corn Belt and Dairy Land Resource Region (region B) have somewhat higher mean total phosphorus concentrations than one would predict from data for the other Land Resource regions (regions A, C and D) only. Equations for this model are:

$$\log_{10} (\text{PCONC}) = -1.805 + 0.0081 (\% \text{ agric.} + \% \text{ urban}) \quad (2)$$

for region B and

$$\log_{10} (\text{PCONC}) = -1.676 + 0.0081 (\% \text{ agric.} + \% \text{ urban}) \quad (3)$$

for regions A, C and D.

This model explains that for drainage areas having similar combined agriculture plus urban land use percentages, streams in region B will have predicted phosphorus concentrations about 37% higher than those in regions A, C and D.

However, the root mean square deviation using this model is only 0.26 as compared to 0.27 for the first model (1), which means it is not appreciably better for prediction. In other words, although the model does predict somewhat different average phosphorus concentrations because of some regional characteristics, the unexplained variation around this prediction is so great that the change is really not significant. Differences in predicted values using the two models are shown in Table 3.

TABLE 3. PREDICTED MEAN TOTAL PHOSPHORUS CONCENTRATIONS (mg/l) FOR SIMPLE AND REGIONAL MODELS

% Ag + % Urb	Avg. PCONC	Simple Model	Regional Model
		Avg. PCONC in Region B	Avg. PCONC in Regions A, C and D
0	0.015	0.021	0.016
25	0.025	0.034	0.025
50	0.043	0.054	0.040
75	0.074	0.085	0.063
100	0.126	0.136	0.101

Finally, a model which incorporates every variable on file in this study (listed in Appendix A) that has a statistically significant effect, adjusted for other related variables on file, is the following:

$$\text{Log}_{10} (\text{PCONC}) = -2.576 - 0.0046 \text{ slope} + 0.0021 \text{ precip.} + 0.129 \text{ pH} + 0.0071 (\% \text{ agric.} + \% \text{ urban}) \quad (4)$$

The correlation coefficient for this model is 0.75 and the root mean square deviation is 0.255 meaning that again, predictions using this model are not appreciably better than those derived from the simple model. Inclusion of this model is primarily to show the effect of the statistically significant variables used, holding everything else constant. It

is notable that inclusion of the surface soil pH value makes it unnecessary to fit a different model for region B. Also interesting is the fact that after adjusting for "% agriculture plus % urban", the effect of animal unit density is not statistically significant for total phosphorus concentrations. Animal unit density had a significant effect on total phosphorus concentrations for the data (on 143 drainage areas) collected for Working Paper No. 25 (Environmental Protection Agency, 1974). This may have been due to the fact that most of the agricultural areas included in the Working Paper No. 25 data set were dairy oriented. With the present data set (473 subdrainage areas) it is probable that other agricultural characteristics have masked the effects of animal unit densities.

Figure 23 shows the relationship between mean total nitrogen concentrations and "% agriculture plus % urban". The equation for the regression line shown in Figure 23 is:

$$\log_{10} (\text{NCONC}) = -0.278 + 0.0088 (\% \text{ agric.} + \% \text{ urban}) \quad (5)$$

The correlation is stronger ($r = 0.83$) than that shown for phosphorus concentrations (Figure 22), and there is noticeably less variation around the regression. Thus, the model does a little better in predicting than did the simple model for phosphorus. The utility of this equation for predicting mean total nitrogen concentrations is shown in Table 4.

TABLE 4. PREDICTED MEAN TOTAL NITROGEN CONCENTRATIONS (mg/l)

% Ag + % Urb	Avg. NCONC	67% Limits	95% Limits
0	0.53	0.35-0.80	0.24-1.19
25	0.87	0.58-1.31	0.39-1.96
50	1.45	0.97-2.18	0.64-3.26
75	2.41	1.61-3.62	1.07-5.42
100	4.00	2.67-6.00	1.78-9.00

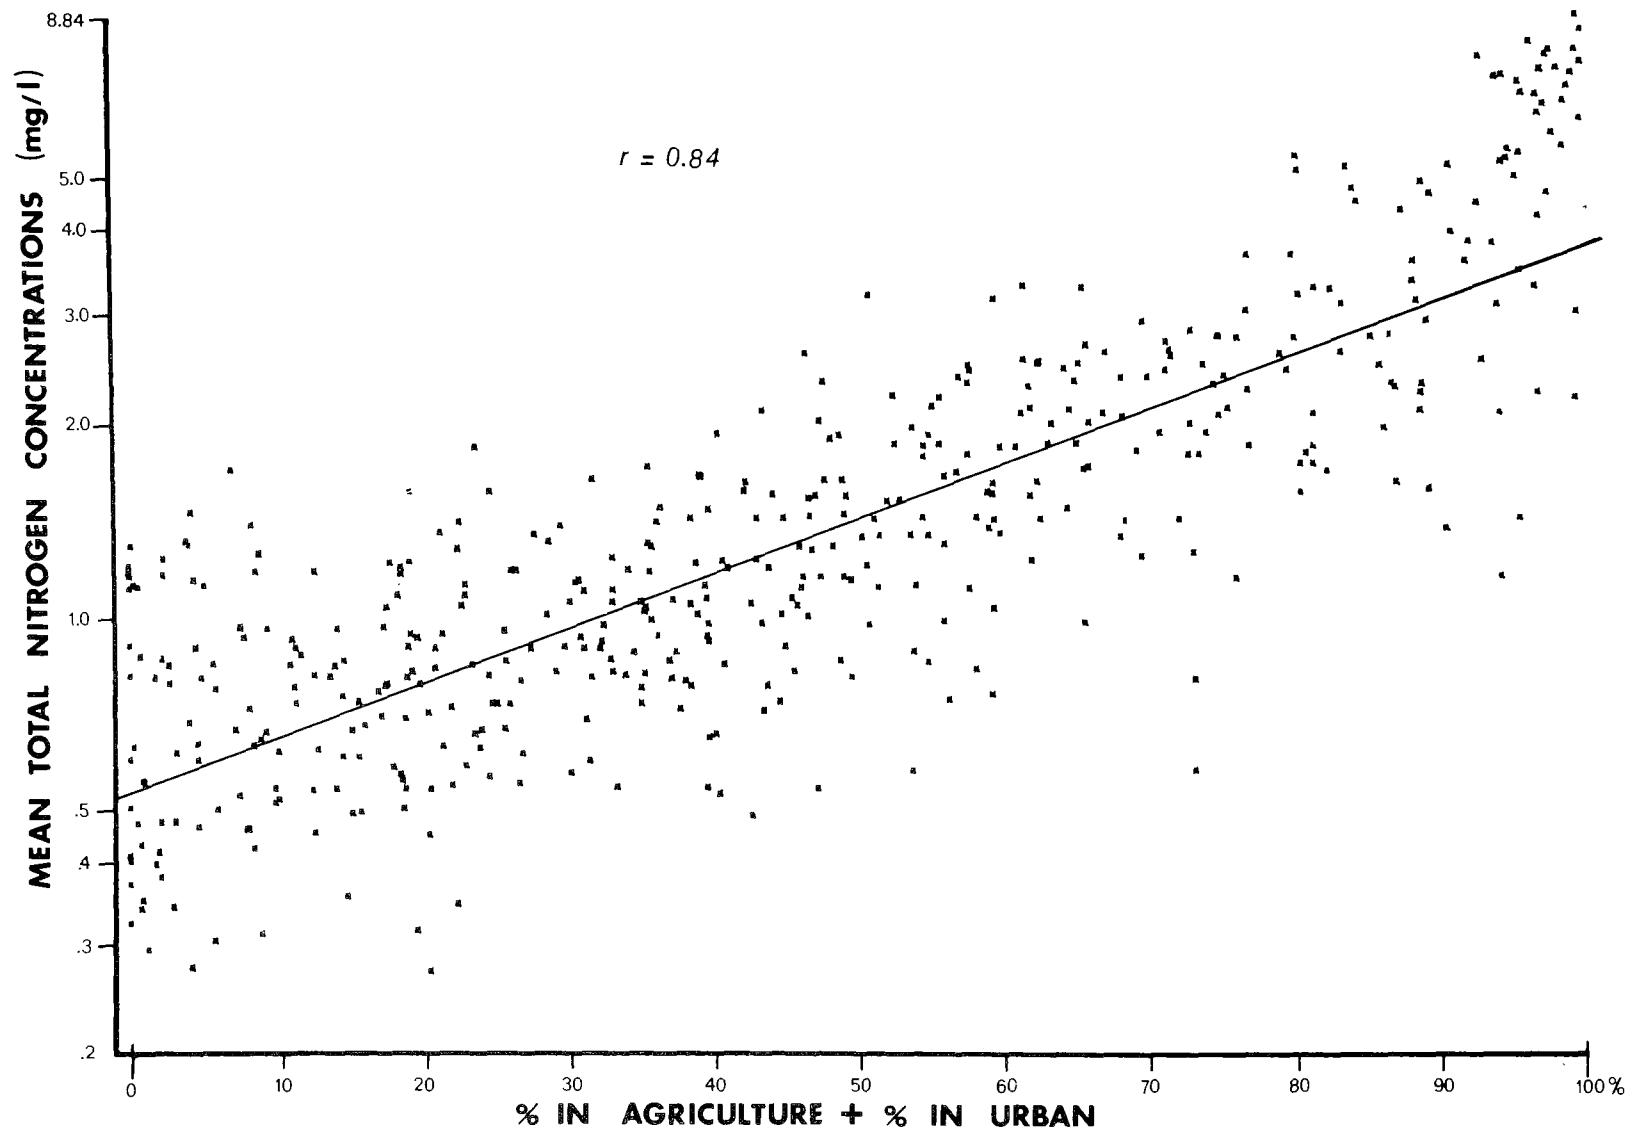

Figure 23. Scattergram of "contributing" land use types related to nitrogen concentrations in streams.

The next most complex model, as was the case with phosphorus, fits one regression line for region B and another for regions A, C and D. However, the two equations for predicting total nitrogen concentrations not only have different intercepts, but different slopes as well. One partial explanation is that the effect of "% agriculture + % urban" on nitrogen concentrations is not linear over a very wide range.

The equations for the regional model are:

$$\text{Log}_{10} (\text{NCONC}) = -0.331 + 0.0101 (\% \text{ agric.} + \% \text{ urban}) \quad (6)$$

for region B and

$$\text{Log}_{10} (\text{NCONC}) = -0.236 + 0.0071 (\% \text{ agric.} + \% \text{ urban}) \quad (7)$$

for regions A, C and D.

This regional model, like that for total phosphorus concentrations, does not give appreciably better predictions than the simple model, due to the large amount of unexplained variation. The root mean square deviation for the regional model is 0.17 as compared to 0.19 for the simple model. Differences in predicted values using the two models are shown in Table 5.

TABLE 5. PREDICTED MEAN TOTAL NITROGEN CONCENTRATIONS
(mg/l) FOR SIMPLE AND REGIONAL MODELS

% Ag + % Urb	Avg. NCONC	Simple Model	Regional Model
		Avg. NCONC in Region B	Avg. NCONC in Regions A, C & D
0	0.53		0.58
25	0.87	0.83	0.87
50	1.45	1.49	1.32
75	2.41	2.67	1.98
100	4.00	4.77	2.98

A third model using all variables on file which are statistically significant, adjusted for other related variables on file, is the following:

$$\log_{10} (\text{NCONC}) = 0.237 - 0.0018 (\% \text{ Forest}) - 0.002 \text{ slope} - 0.0018 \text{ precip.} - 0.0012 \text{ animal unit density} + 0.0013 (\% \text{ agric.} + \% \text{ urban}) + 0.000055 (\% \text{ agric.} + \% \text{ urban})^2 \quad (8)$$

This model has a root mean square deviation of about the same as the previous two models (0.17) and a correlation coefficient of 0.84, indicating it is not significantly better for predictive purposes than the simple model. It does show, however, which variables have statistically significant effects when other variables are held constant. It is interesting to note that animal unit density has a significant effect on mean total nitrogen concentrations¹.

Figures 24 and 25 show the relationships between "% agriculture plus % urban" and both mean orthophosphorus concentrations and mean inorganic nitrogen concentrations. The equation for the regression line shown in Figure 24 is:

$$\log_{10} (\text{OPCONC}) = -2.208 + 0.0089 (\% \text{ agric.} + \% \text{ urban}) \quad (9)$$

The equation for the regression line shown in Figure 25 is:

$$\log_{10} (\text{INCONC}) = -0.873 + 0.0136 (\% \text{ agric.} + \% \text{ urban}) \quad (10)$$

The correlation coefficients ($r = 0.70$ for OPCONC and % agric. + % urban, and 0.82 for INCONC and % agric. + % urban) for these relationships are a little lower than similar relationships for total phosphorus and total nitrogen shown in Figures 22 and 23.

¹ Data from the three drainage areas with extremely high animal unit densities were not used to fit the above model. In these three cases, county figures were apparently not appropriate and gave distorted animal unit density values.

"Contributing" Land Use Types and Nutrient Export

Figures 26 through 27 illustrate the relationships between nutrient export and "% agriculture plus % urban". These figures show less significant relationships between nutrient export and "contributing" land use than were shown between nutrient concentrations and "contributing" land use. From an earlier analysis of overall land use and nutrient runoff, lower correlations ($r = 0.41$ between total P export and "% agric. + % urban", 0.36 between orthophosphorus export and "% agric. + % urban", 0.46 between total nitrogen export and "% agric. + % urban", and 0.61 for inorganic nitrogen export and "% agric. + % urban") were to be expected. Because of the covariants mentioned earlier, and other effects on the "flow" portion of the export computation, a more accurate method of predicting export values (or stream loads) would be to use the appropriate model for concentration prediction and then multiply by flow. Stream flow data are available for most of the United States from the U.S. Geological Survey. For drainage areas where flow data are not available, good estimates can be made for USGS flow records on overlapping, adjacent, or nearby areas, together with some general knowledge of the topographic and climatic characteristics of the particular area.

Regionality

Figures 28 and 29 illustrate the regional aspects of the two simple models [(1) and (5)] for predicting nutrient concentrations in streams from combined percentages of agricultural and urban existing land use. These maps offer some qualitative refinement of the models by revealing, on the basis of data gathered for this study, geographical areas where nutrient concentrations can be expected to be greater, much the same as, or less than those predicted by the models.

The data in Figure 28 illustrate some fairly obvious regional patterns. They indicate that phosphorus concentrations in streams are generally

LG

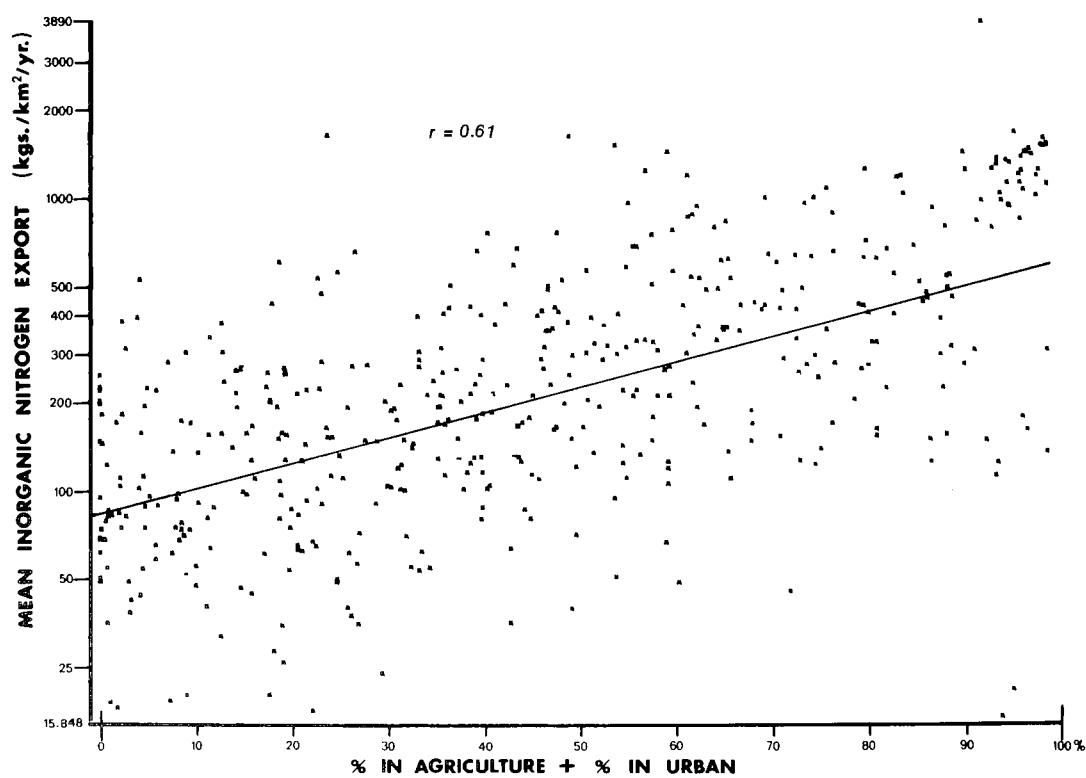

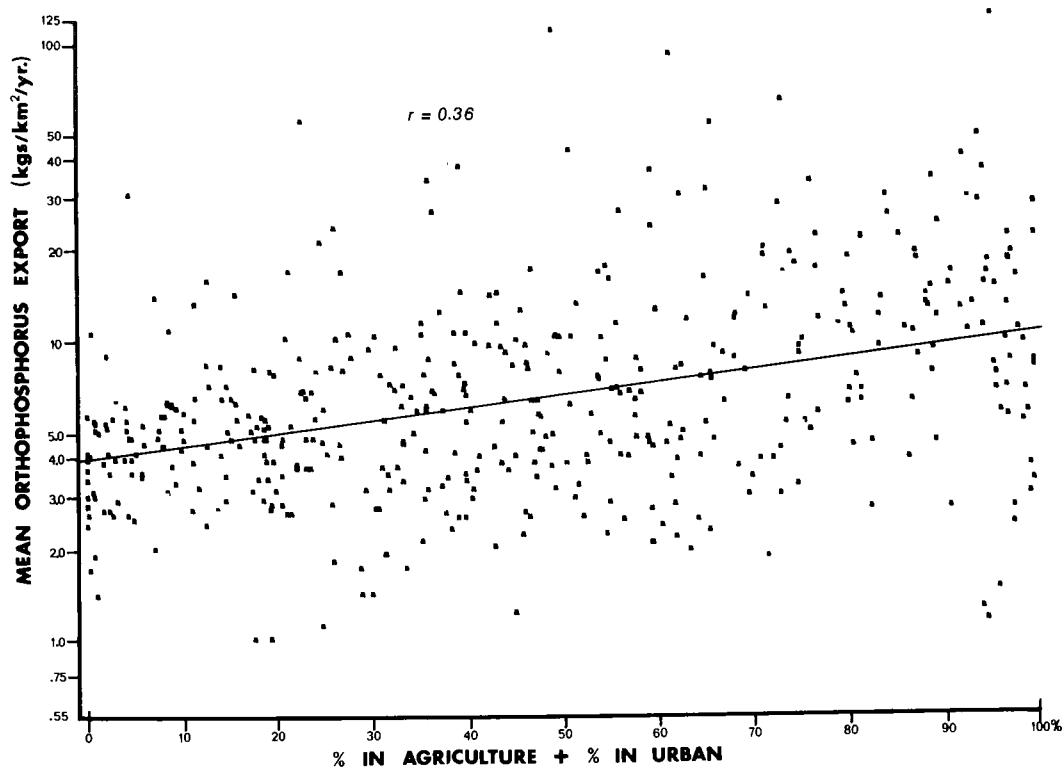

Figure 27. Scattergram of "contributing" land use types related to stream exports of orthophosphorus and inorganic nitrogen.

higher than those predicted by the prediction model in a region extending from eastern Ohio through central and southern Indiana to southern Illinois. This region may extend around through the western tips of Kentucky and Tennessee into Mississippi, north-central Alabama and parts of northern Georgia. Another area where phosphorus concentrations are generally higher than those predicted by the model comprises much of Wisconsin and south-central and southeastern Minnesota. Still another "high" area may exist in a region extending from west-central Virginia through eastern Virginia and into central Delaware, but large gaps in data points make definition of this area difficult to support. A very large region where phosphorus concentrations are nearly the same as, or lower than, those predicted by the model includes most of the Northeast from West Virginia, Maryland, and Pennsylvania through Maine, with the exception of the area centered on southeastern New York and Connecticut. Other smaller areas where phosphorus concentrations are mostly lower than those predicted, are central Illinois, central Ohio, west-central Tennessee, and a small region extending from south-central Kentucky to the northwestern tip of Georgia.

The regional patterns were even more evident for total nitrogen (Figure 29) than they were for total phosphorus (Figure 28). Interestingly though, the regional patterns illustrated by residuals of the nitrogen prediction model show little to no resemblance to those of the phosphorus model. It is also noteworthy that, neither map reveals patterns that appear to have any clear correlation with map units of the macro-aspects (such as physiographic regions, climatic characteristics, soil types, and geology), that one might expect to affect the regional patterns of the residuals.

Figure 29 reveals two major areas where the data show nitrogen concentrations in streams to be near or above those predicted by the model. The first area is centered on eastern Pennsylvania, New Jersey and southeastern New York and includes much of Delaware, east-central Maryland, central Pennsylvania, northeastern New York and Connecticut. The second area extends from southeastern Wisconsin, through central

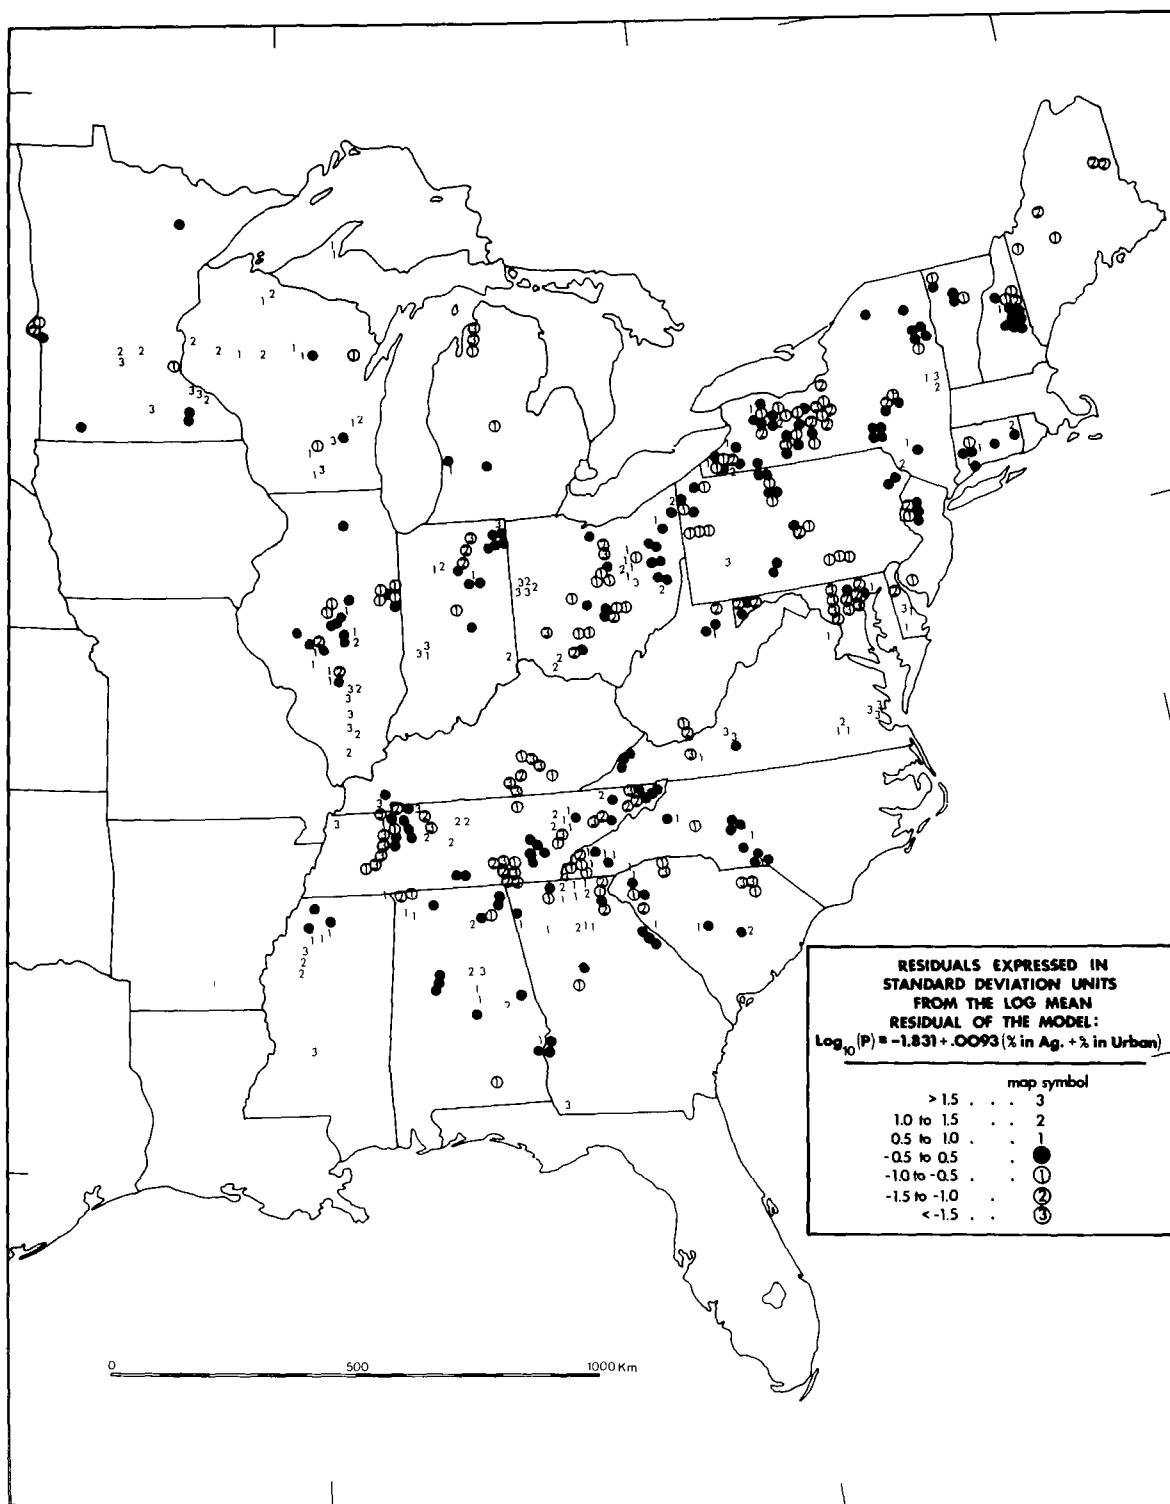

Figure 28. Areal distribution of residuals from a prediction model for total phosphorus concentrations in streams studied in the eastern United States.

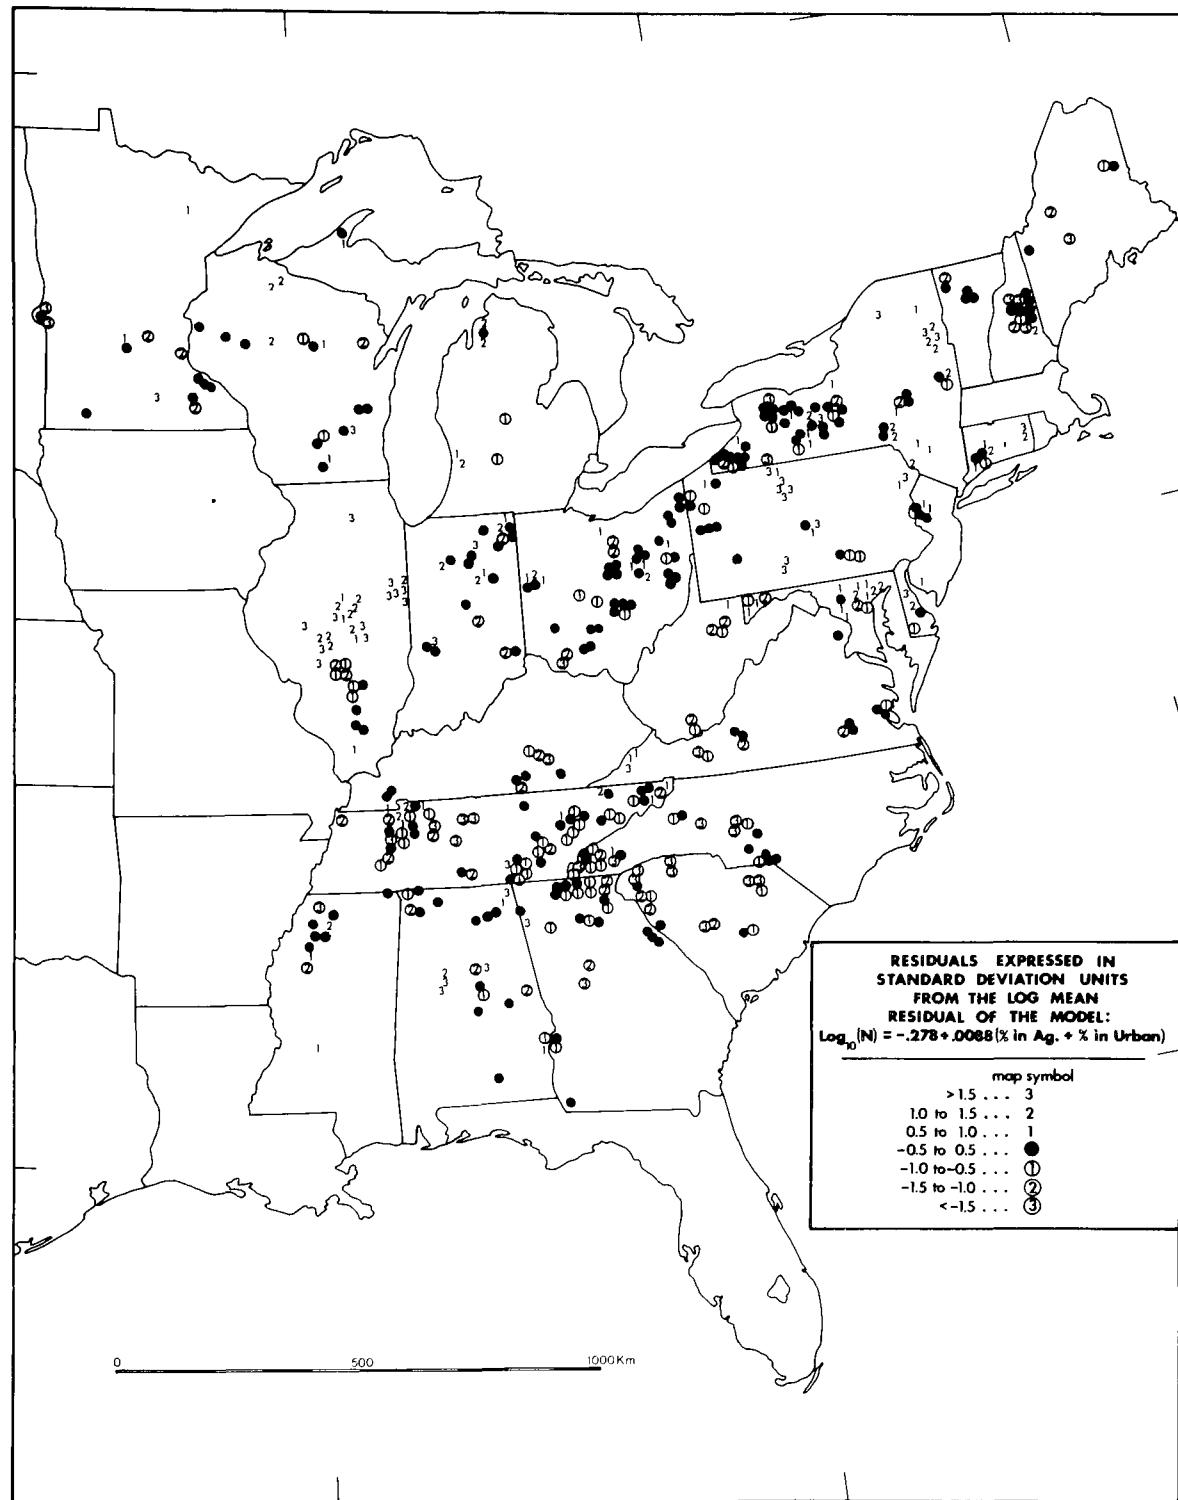

Figure 29. Areal distribution of residuals from a prediction model for total nitrogen concentrations in streams studied in the eastern United States.

Illinois, south-western Michigan, north-central Indiana and west-central Ohio. Data on the central and eastern Illinois part of the latter region show nitrogen concentrations in streams in that area to average much higher than would be predicted from the model. Data on Figure 29 also suggest that throughout most of the Appalachian highlands, and adjacent parts of the Piedmont, southern Illinois, southern Indiana and southern Ohio, nitrogen concentrations in streams can be expected to be near or below what one would predict from the model. Another area of lower nitrogen concentrations consists of the extreme northeastern New England states of Vermont, New Hampshire and Maine.

Although the models presented illustrate a significant increase in the predictability of nutrient concentrations in streams through the use of land use parameters, rather than simply using mean values of data points regardless of land use parameters, the models only indicate correlations found between existing land use patterns and nutrient concentrations in streams. It does not necessarily follow that the models can be used to predict changes in concentrations with associated changes in land use. However, gross predictions of this nature may be aided by analysis of the raw data (Appendix A) together with some of the individual relationships and regional patterns which have been illustrated

Nutrient Runoff--Soils Relationships

The preliminary analysis of the relationships between soils and nutrient concentrations in streams, discussed in Working Paper No. 25, indicated significant correlations between pH characteristics in soils and nutrient concentrations in streams. Generally, concentrations were found to be considerably higher in streams draining areas with soil orders characteristically high in bases, than in streams draining areas with mostly acid-type soils. Efforts were therefore made to include consideration of surface soil pH in the analysis of results in this follow up study. It was found that even a good approximation of mean

surface soil pH for each of the 473 drainage areas was not available except through time-consuming work with numerous large-scale maps from widely scattered sources and contact with local soils scientists. The time and expense ruled this approach out, at least for the present.

Considering time and expense, the best available source was a collection of estimates of surface soil pH ranges for map units appearing on the National Atlas soils map (Smith, 1975; and U.S. Geological Survey, 1970). Each drainage area was identified with a midpoint of the pH range for the soils map unit predominant within it. This system left much to be desired for the actual surface soil pH values probably varied considerably with land use within the area covered by a given soils map unit. For instance, for a given soils map unit in central South Carolina, the surface soil pH is probably a great deal higher in the active cropland areas than in the parts where pine forests predominate. Even with these limitations, which if anything would have a "diluting" effect on the pH to stream nutrient concentration correlations, there appear to be sufficiently significant correlations to warrant a more detailed examination of the relationship. The correlation coefficients for the relationships between surface soil pH and mean nutrient concentrations in streams were as follows:

pH and Total Phosphorus, $r = 0.58$

pH and Orthophosphorus, $r = 0.57$

pH and Total Nitrogen, $r = 0.61$

pH and Inorganic Nitrogen, $r = 0.55$

Nutrient Runoff--Geology Relationships

Discussions of water quality differences from one lake watershed to another, particularly with respect to nitrogen and phosphorus loads and concentrations, often include some mention of geological effects. However, little data are available on the specific effects of geology

on nutrients in either lakes or streams. One of the few articles written on the subject (Dillon and Kirchner, 1975) has suggested a strong effect of geology on phosphorus loads in streams. It was the strength of Dillon and Kirchner's conclusions, together with the suitability of their system to NES non-point source study data, that motivated the inclusion of geology as a macro-aspect to be considered in this paper.

Tables 6 and 7, from Dillon and Kirchner, illustrate the results of their findings.

TABLE 6. RANGES AND MEAN VALUES FOR EXPORT OF TOTAL PHOSPHORUS FROM 31 SOUTHERN ONTARIO WATERSHEDS (kg/km²/yr)

Land Use	Geological Classification	
	Igneous	Sedimentary
Forest		
Range	2.5-7.7	6.7-14.5
Mean	4.8	10.7
Forest + Pasture		
Range	8.1-16.0	20.5-37.0
Mean	11.7	28.8

TABLE 7. RANGES AND MEAN VALUES FOR EXPORT OF TOTAL PHOSPHORUS FROM 43 WATERSHEDS. VALUES INCLUDE DATA GIVEN IN TABLE 6 AND ADDITIONAL DATA FROM THE LITERATURE (kg/km²/yr)

Land Use	Geological Classification	
	Igneous	Sedimentary
Forest		
Range	0.7-8.8	6.7-18.3
Mean	4.7	11.7
Forest + Pasture		
Range	5.9-16.0	11.1-13.0
Mean	10.2	23.3

These data indicate a strong effect of the sedimentary geology classification on phosphorus loads in streams. Generally their mean values for sedimentary watersheds were between 2 1/4 and 2 1/2 times greater than those from igneous watersheds. It should be noted that the igneous watersheds shown in Tables 6 and 7 are of plutonic origin. Additional data from the literature led Dillon and Kirchner to conclude that one would expect phosphorus loads in streams draining igneous watersheds of volcanic origin to be 15 times greater than in streams draining igneous watersheds of plutonic origin.

Table 8 was prepared to illustrate the possible effects of geology on nutrient concentrations and loads in streams with respect to data collected by the NES on 473 non-point source-type drainage areas in the eastern United States. The drainage areas were identified according to the geological classification outlined earlier in this paper. The numbers shown after the classification provide a coding scheme for handling combinations. The data were grouped by overall land use category to hold land use as constant as possible. Data were not presented for drainage areas in mixed, mostly urban, and mostly agriculture categories because of the greater variability of land use within these categories.

Generally, data in Table 8 indicate that given this classification scheme and the NES data, there is no apparent significant effect of geology on either phosphorus or nitrogen loads in streams. The same appears true for phosphorus and nitrogen concentrations. Although there was a paucity of purely igneous watersheds, there were many where igneous rocks were present, or even represented the predominant type; enough it was felt, to see an effect of this classification if existent. By looking at the "mostly forested" data set, which contains the largest number of predominantly igneous-plutonic watersheds, one can see little difference in mean total phosphorus concentration or export values between sedimentary watersheds and igneous-plutonic watersheds. Interestingly, although the mean total phosphorus export

TABLE 8. GEOLOGIC CLASSIFICATION AND MEAN VALUES FOR STREAM NUTRIENT CONCENTRATIONS AND EXPORTS FROM 223 SUBDRAINAGE AREAS IN THE EASTERN UNITED STATES. DATA GROUPED BY OVERALL LAND USE CATEGORY

Abbreviations:

T-P = Total Phosphorus
O-P = Orthophosphorus

T-N = Total Nitrogen
I-N = Inorganic Nitrogen

value was about 25% greater for sedimentary watersheds than for igneous-plutonic watersheds, the mean orthophosphorus export value was about 27% less. Analysis of the remaining data revealed no significant differences in orthophosphorus to total phosphorus relationships with different geological classifications.

It was difficult to study these data for the possible effects of igneous rocks of volcanic origin (as compared with igneous rocks of plutonic origin) on stream nutrient concentrations or loads. No drainage areas in either the "forest" or "mostly forest" data sets were classified as completely or predominantly igneous-volcanic. However, there were four drainage areas in one data set where igneous rocks of volcanic origin were present but not predominant. Comparison of these data with those of other geological classifications revealed relatively insignificant differences.

It should be emphasized that the above analysis does not suggest that geology has no effect on nutrient concentrations or loads in streams. It does point out that no clearly significant effects are apparent using this type of classification and the NES data. That the NES data did not support the conclusions in Dillon and Kirchner's paper regarding phosphorus export may lie in the method of classification.

Perhaps a more appropriate classification scheme should be based on the mineral composition of the rocks rather than being based entirely or primarily on origin. A simplified version of such a scheme might have just two groups or classes--a class containing rocks generally considered as being high in phosphorus content and a class containing rocks having very little phosphorus. Rocks included in the first, or "high phosphorus", group would be the gabbros, diorites, and basalts, or rocks largely composed of ferromagnesian minerals and containing considerable apatite (Taylor, 1975; and Goldschmidt, 1958, pp. 454-459). Apatite is the mineral containing nearly all of the phosphorus in igneous rocks (Rankama and Sahuma, 1950, pp. 584-586). Common rocks in the "low phosphorus" group would be granite, syenite, granodiorite, rhyolite and andesite; or rocks

largely made up of aluminosilicate minerals and containing little to no apatite. Apparently all of the southern Ontario watersheds classified igneous by Dillon and Kirchner contained "low phosphorus" rocks. Metamorphic rocks might be fit into one of the above groups depending on the type or types of rocks metamorphosed.

Although this scheme represents a better breakdown of igneous and some metamorphic rocks for studying the effects of general rock types on phosphorus in streams, it may present difficulties. For many parts of the United States, geologic maps with the level of detail necessary to accomplish this breakdown, may be lacking or difficult to obtain.

15. SUPPLEMENTARY NOTES			
16. ABSTRACT National Eutrophication Survey (NES) data for 473 non-point type drainage areas in the eastern United States were studied for relationships between drainage area characteristics (particularly land use) and nutrient levels in streams. Both the total and inorganic forms of phosphorus and nitrogen concentrations and loads in streams were considered. The objectives were to (1) investigate these relationships, as they were evidenced by the NES data and (2) develop a means for estimating stream nutrient levels from knowledge of "macro" drainage area characteristics. Mean nutrient levels were considerably higher in streams draining agricultural watersheds than in streams draining forested watersheds. The levels were generally proportional to percentages of land in agriculture, or the combined percentages of agricultural and urban land use. Variations in nutrient loads (exports) in streams, associated with differences in land use categories, were not as pronounced as the variations in nutrient concentrations. This was apparently due, in large part, to differences in areal stream flow from different land use types. Regression analysis of the combined percentages of agricultural and urban land uses against both the total and inorganic forms of phosphorus were performed. Equations for these analyses, together with maps illustrating the equations residuals offer a limited predictive capability and some accountability for regional characteristics.
